The century birthday of a Scottish medical poet.—January 5, the birthday of Dr. David Macbeth Moir, the medical poet, whose birthplace was Musselburgh, Scotland, was set apart by many literary and scientific men to commemorate the beloved physician of their section, by the founding of a scholarship. Dr. Moir's sonnet on "The Hospice of Saint Bernard" is the writing especially noted as containing the spirit and warmth of a "medical poet." "Delta," as he signed himself in some of his writings, was born in 1798 and died in 1851.

The Pirogoff memorial: Billroth's sentiment.—The museum of anatomy and surgery recently built to the memory of Pirogoff and to be called the Pirogoff Museum was opened in St. Petersburg on Sunday, October 26 (old style). The total funds collected for the memorial were 115,000 roubles and the building has cost 85,000 roubles (about £9,000). The opening

ceremony was attended by the Prince and Princess of Oldenburg and a large number of other distinguished guests. It is not generally known that the famous Viennese surgeon Billroth was a great admirer of Pirogoff, but that this was the fact is attested by the interesting sentiment or endorsement, made by the former when presenting his picture to his friend and patient Pirogoff, that runs as follows: "To the honored Master, Nicholas Pirogoff. Truth and clearness in thought and in feeling, as well as in word and deed, are the steps on the ladder which lead men up to a seat with the gods. To follow your guidance, equally courageous and sure, on this path, which is not without its dangers, is my earnest intention. Your sincere admirer and friend, Billroth." In writing to a Russian surgeon regarding the fatal malady of Pirogoff, a palatal neoplasm, he refused to operate or to advise an operation, saying "I am not that bold operator whom you knew years ago in Zurich. Before deciding on the necessity for an operation, I always propose to myself this question, Would you permit such an operation as you intend performing on your patient to be done on yourself? Years and experience bring in their train a certain degree of hesitancy (Zurückhaltung). Every year brings out clearer and clearer the shortcomings of our art."

The last of the Valois and his assassin.—Recently some interesting facts have been made known in regard to the assassination of King Henry of Valois, at St. Cloud, Aug. 1, 1589. It would appear that the king was slain by a man who was, like himself, intensely neurotic. Henry III. is one of the best known historic bad characters. His face was small and unymmetric; his tastes varied between violent exercise in the worst weather and the effeminate coddling of himself in midsummer. Abject superstition made him walk barefoot at the head of a procession, and a few days later he would delight in swearing complicated oaths with intent to insure his final reprobation. He rouged his face, and wore kid gloves in bed to keep his hands white, and was subject to the worst perversions of instinct. But Jacques Clement, his assassin, was also, it would appear, a being who lived on the borderland of crime and insanity. The religious monomania, undeniably the immediate cause of the crime, followed a life of license alternated with extreme mortification of the flesh. It was said at the time that a court ecclesiastic had hounded him to cause him to dream, and to fancy that he heard voices. The truth is that his mind, weakened by vice and bigotry, was thoroughly unhinged by the horrors of the religious wars of his time, and he sincerely believed that heaven had ordered him to slay a man who, both from a medical and a moral point of view, was his perfect counterpart. Acting on that belief Clement made history by extinguishing the line of the Valois. —*British Medical Journal.*

Washington.

MEDICAL SOCIETY ELECTION.—At the annual meeting of the Medical Society recently held, the election of officers resulted as follows: President, Dr. Samuel C. Busey; vice-presidents, Drs. Charles W. Richardson and G. M. Kober; corresponding secretary, Dr. Thomas C. Smith; recording secretary, Dr. Samuel C. Adams; treasurer, Dr. C. W. Franzoni; librarian, E. L. Morgan; censors, Drs. C. W. Richardson, Winter, French, Kleinschmidt and Acker. Dr. Busey was president of the Society some years ago, and this election gives him the office for the sixth term, five of which have been consecutive. Dr. Franzoni was re-elected to serve his twenty-sixth term as treasurer, and Dr. Adams was re-elected to serve a ninth term as recording secretary. At this, one of the largest attended meetings in the history of the Society, the almost unanimous election of these officers is a fitting testimonial of their fidelity to duty and the recognition of their valuable services. Dr. Robbins read a paper entitled "Dangers of the Barber Shop;" Dr. Snyder, "Abscess of Gall-bladder with Typhoid Ulcers;" and Dr. J. Taber Johnson reported two cases of hysterectomy, with specimens.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 27th meeting of the Society was held at the residence of Dr. Bromwell, at which Dr. W. S. Bowen read a valuable paper on "Ventral Hernia."

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—At the recent meeting of the directors of the hospital, the following report for the month of December was read: New cases, 726; total number of visits, 2,174; number of deaths, 1; number of operations, 155; ward patients, 37; number of prescriptions, 2,351; ambulance calls, 45. The directors decided to have the annual donation day February 16, at which time donations of money, clothing, medical supplies and instruments will be gratefully received. The list of donations and donors will appear in the public press.

CHANGE OF ADDRESS.

Baker, L. H., from Oak Park, Ill., to Fitzgerald, Ga.
Capp, W. M., from 2211 Spruce Street to 123 N. 11th Street, Philadelphia.
Eichberg, L. R., from 211 E. 62d Street, to 225 W. 106th Street, New York.
Formanek, F., from 251 Ogden Avenue, to 803 Warren Avenue, Chicago.
Fite, C. C., from 102 W. 93d Street to 1 Madison Square, New York.
N. Y.; Frank, C. P., from 77 E. High Street to 167 E. High Street, Detroit, Mich.
Hoffman, F. N. A., from Evanston to Stewardson, Ill.
McDaniel, E. D., from Camden to Coy, Ala.; Motter, M. G., from 30th and U Streets, N. W. to 2114 Connecticut Avenue, N. W. Washington, D. C.
Nehensky, H., from 165 Hudson Avenue to 28 Erving Place, Chicago.
Nolder, S. M., from Fairmount, Ind., to 500½ Main Street, Newton, Kas.
Proctor, C. M., from Helene to White Sulphur Springs, Mont.
Stewart, H. J., from 105 S. Campbell Avenue to 2118 W. Lake Street, Chicago.
Thomas, C. H., from Philadelphia, Pa., to Dansville, N. Y.; Tomlin, W. S., from North and Illinois to 48 W. North Street, Indianapolis, Ind.
Van Hood, E., from Ocala, Fla., to 214 E. 34th Street, New York City.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from January 8 to 14, 1898.

Major Egon A. Koerper, Surgeon (Ft. Crook, Neb.), leave of absence granted is extended two months.
Lieut.-Col. David L. Huntington, Deputy Surgeon-General (Surgeon-General's office, Washington, D. C.), is granted leave of absence from or about Feb. 1 to April 10, 1898.
Capt. Peter R. Egan, Asst. Surgeon, is relieved from duty at Ft. Hamilton, N. Y., and assigned to duty at Ft. Hancock and the Sandy Hook Proving Ground, N. J., with station in New York City, and will make daily visits to and between those points until he shall be furnished with suitable quarters at Ft. Hancock.
Col. Dallas Baché, Asst. Surgeon-General, will be relieved from duty as chief surgeon, Dept. of the Platte, on Jan. 20, 1898, and will report to Washington, D. C., and report in person to the Surgeon General of the Army, to assume charge of the museum and library division of his office, to enter upon duty April 10, 1898, as professor of military medicine in the Army medical school, to which he is assigned accordingly.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending January 15, 1898.

Medical Director R. H. Kidder, detached from duty with the medical examining board, Washington, January 21, and ordered home on waiting order.
Medical Director B. H. Kidder, retired January 23.
P. A. Surgeon A. W. Dunbar, detached from the "Vermont" and ordered to the "Nashville" January 15; on arrival of the "Nashville" on the European station ordered to the "San Francisco."

BACILLUS ICTEROIDES AND BACILLUS X.

BY GEO. M. STERNBERG, M.D., LL.D.

SURGEON-GENERAL U. S. ARMY.

WASHINGTON, D. C.

In order that there may be no misapprehension upon the part of bacteriologists who are now engaged in researches relating to the etiology of yellow fever, I give below a brief extract from a paper which I shall send to the *Centralblatt für Bakteriologie* for publication.

EXTRACT.

As stated in my previous paper, my information relating to Sanarelli's bacillus, when this paper was written, was obtained from a translation in the *British Medical Journal*, of his "Address" given before the University of Montevideo, June 10, 1897. I have since read his paper in the *Annales* of the Pasteur Institut, and upon my return from Europe in September I passed through Paris, and through the courtesy of Dr. Roux obtained a culture of the "bacillus icteroides" which had recently been sent to the Pasteur Institut by Dr. Sanarelli. I now recognize the fact that there are certain cultural differences, some of which have been pointed out by Sanarelli in his paper in that journal. At present bacillus X is non-motile, while Sanarelli's bacillus is actively motile. But in my original cultures, as stated in my published report, bacillus X was motile. The presence of flagella may now be demonstrated by proper staining methods.

In judging of cultural differences now existing, it must be remembered that bacillus X has been cultivated in artificial media for eight years. In the comparative study now being made in the pathologic laboratory of the Army Medical Museum in this city, the peculiar seal-like colonies, to which Sanarelli attaches so much importance, have not been observed in cultures of bacillus X. Again, bacillus X causes gas production in lactose bouillon, while Sanarelli's bacillus does not.

In view of these facts complete identity in biologic characters can not be maintained.

The next question which arises is, whether the bacillus obtained by Sanarelli from yellow fever cadavers in Rio de Janeiro, and by me from yellow fever cadavers in Havana, are varieties of the same species. Comparative experiments are now being made under my direction with a view to determining this question.

In my opinion bacteriologists are often too much inclined to differentiate species upon slight cultural differences, such as the appearance of colonies, ferment action, etc. Sanarelli himself has shown us, in his paper published in the *Annales* of the Pasteur Institut, three varieties of the colon bacillus, which may be distinguished by differences in the colonies formed upon gelatin plates. Every experienced bac-

teriologist knows that varieties of all the best known species of bacteria exist and that these may differ as to their pathogenic power, the rapidity and character of their growth in various culture media, their power to produce pigment, the production of acid, of gas, etc.

If bacillus X and Sanarelli's bacillus icteroides are not even varieties of the same species, the question will remain whether one, or the other, or neither, is concerned in the etiology of yellow fever.

It is evident that neither has a claim worthy of serious consideration upon any other ground than that which relates to its pathogenic action. Sanarelli's claim is based chiefly upon his inoculation experiments upon the lower animals and upon man, and his results deserve the most careful consideration. Comparative experiments upon dogs, rabbits and guinea pigs are now being made, under my direction, with Sanarelli's bacillus and with my bacillus X. It is my intention to publish full details of these experiments hereafter. At present I must content myself with an account of some preliminary experiments which show that bacillus X has remarkable pathogenic properties when tested upon dogs by Sanarelli's method (injection into a vein). These experiments have been performed in the pathologic laboratory of the Army Medical Museum by Maj. Walter Reed, surgeon U. S. A., in charge, assisted by Dr. James Carroll, hospital steward U. S. A., and the record given below has been made for me by Dr. Reed.

Experiment 13. July 23, 1897, 1:20 P. M. Young dog, No. 327, weight thirteen pounds, inoculated into ear vein with 5 c.c. of a twenty-four hour culture in glucose bouillon of X from blood of rabbit 314. A very active lively animal. At 1:35 P. M. appears very sick, lying down, does not respond to voice. At 2:05 P. M. vomits considerable quantity of partially digested food, followed by fluid stool with tenesmus. At 2:23 P. M. a small brown watery stool. This repeated at short intervals with much tenesmus. At 2:51 P. M. and 3:05 P. M. vomits with much effort a small quantity of grayish frothy fluid mixed with mucus; 3:30 P. M. vomits; 4 P. M. dog lies on its side with extremities rigidly extended. Temperature in rectum 104.1 F.; prior to injection, temperature 101 F. July 24, 9 A. M., temperature 102; refuses food or drink; lies on side with extremities extended; during the day has several thin dark fluid stools containing blood and mucus; 4 P. M. temperature 104; died at 6 P. M., twenty-eight and one-half hours after inoculation.

Autopsy. Thorax: Thymus gland large, dark red; shows a number of small hemorrhages beneath surface. Mediastinal glands swollen, dark red in color. A small hemorrhage over right auricle, which is distended with blood. Left auricle empty. Right ventricle distended, left contracted. Hemorrhages beneath endocardium in latter. Valves normal. Myocardium, pale red. Numerous hemorrhagic areas beneath pleura over right lung. Both lungs, all lobes congested. Lower lobe right lung edematous. On cut section, reddish fluid exuded freely.

Abdomen: Numerous hemorrhages beneath peritoneal surface of duodenum.

Liver: Of a mottled pale and red color, the light color predominating.

Spleen: Enlarged, dark red, firm.

Kidneys: Enlarged, cortex swollen, pale.

Adrenals: Small, pale.

Stomach: Mucous membrane over greater curvature, of uniform dark red color. No erosions to be seen.

Intestines: Duodenum and upper part of jejunum contains considerable quantity of a fluid black tarry material. Mucous membrane of small intestine pale throughout. Peyer's patches not swollen.

From ileo-cecal valve to anus the longitudinal rugae of mucous membrane are the seat of marked hemorrhage, which extends into submucosa. Some fluid blood in large intestine.

Bladder: Contracted, containing about 4 c.c. of albuminous urine. Cultures from blood, liver and spleen show numerous colonies of *X*. Kidney, urine and bile negative.

Microscopic examination of sections shows wide spread necrosis, with fatty degeneration of liver parenchyma and cloudy swelling of renal epithelium.

Experiment 35.—August 6, 1897. Dog No. 347. Weight ten pounds. Injected at 2:45 p. m., with 13 c.c. of a seventy-two hour culture in 2 per cent. lactose bouillon of *X* from rabbit No. 335. Animal much prostrated by injection; 3:05 p. m. vomits food with much retching; again vomits at 3:15 p. m., followed by watery stool containing mucus. Temperature 4 p. m. 96.4 F.; prior to injection, rectal temperature 101 F. Found dead at 8 o'clock following morning, less than eighteen hours.

Autopsy.—Thorax: Subendocardial hemorrhages in left ventricle. Sub-pleural hemorrhages, upper lobe, right lung. Hemorrhagic infarct lower lobe, same lung.

Abdomen: Liver pale, grayish color.

Spleen: Slightly swollen, dark red, soft.

Kidneys: Deeply congested.

Stomach: Contains about 200 c.c. of fluid blood. Mucous membrane throughout of a dark red color. Both small and large intestines contain much fluid blood. Mucous membrane of small intestine swollen and of a uniform dark raspberry red. Less injection of large intestine, though this is quite marked. Bladder contracted, empty.

Cultures positive from blood, liver, spleen and urine. Negative from bile and kidney.

Microscopic examination of sections of liver show cloudy swelling of cells with congestion of capillaries.

These experiments show that bacillus *X* injected into the circulation of dogs produces symptoms and pathologic lesions similar to those produced by equal quantities of a culture of Sanarelli's bacillus. The persistent vomiting, intestinal hemorrhage, albuminous urine (dog 327) and profound changes in the liver cells are certainly very remarkable and give additional weight to the supposition made in my report that "it is possible that this bacillus is concerned in the etiology of yellow fever" (p. 272).

AN IMPROVED METHOD OF DETECTING CASTS IN THE URINE.

BY WALTER S. HAINES, M.D.,

PROFESSOR OF CHEMISTRY IN RUSH MEDICAL COLLEGE,

AND JAMES E. SKINNER, M.D.

FORMERLY FELLOW IN CHEMISTRY IN RUSH MEDICAL COLLEGE,
CHICAGO, ILL.

As is well known, two methods are in use for obtaining the sediment from urine for the purpose of microscopic examination. The oldest and most frequently used is by natural subsidence. A quantity of the urine is placed in a cylindric or conical vessel and allowed to stand at rest for twelve or twenty-four hours, or even longer, when the sediment thrown down is removed by a pipette and a drop or more of it examined under the microscope. The other method is by the use of the centrifuge; the urine being placed in suitable tubes and subjected to rapid revolution the sediment is quickly thrown to the outer ends of the tubes, from which it may readily be removed by a pipette and placed under the microscope for examination.

Each of these methods has its advantages and each its disadvantages. The method by subsidence has the advantage of permitting a large amount of urine to be operated on, but it requires much time and the

deposit produced, especially in urine from cases of interstitial nephritis, is apt to be very light and occupy a considerable space, so that the microscopic examination of two or three drops of it reveals the character of but a small fraction of the entire sediment, easily permitting casts and other elements to escape detection when they are sparingly present.

In quickness of application and concentration of sediment to a small bulk, easy of exhaustive examination under the microscope, the use of the centrifuge is greatly to be preferred, and on these accounts it has of late years come more and more into general use. It has, however, one serious drawback, particularly in searching for casts when sparingly present, and that is the small amount of urine from which the sediment is obtained. In most centrifuges the tubes for holding the urine are of not more than 15 c.c. capacity, and since in using them they are never completely filled the sediment obtained, even when two of the tubes are used, represents only from 20 to 25 c.c. of the fluid under examination. It is perfectly obvious that in looking, for example, for casts in a case of suspected cirrhosis of the kidney, negative results from comparatively so small an amount of urine would not be of great value; 200 or 300 c.c. of the urine might reveal the presence of casts while 30 c.c. might show none.

During the past two years a combined subsidence and centrifuge method has been devised and put in use by us which leaves little or nothing to be desired for ease and certainty in detecting casts. While of much value in examining for casts in any specimen of urine, it is particularly useful in those many and perplexing doubtful cases in which casts, if present at all, are very sparingly found and which, by either of the usual methods, can be detected, if at all, only after repeated and tedious microscopic examination.

Our method is practiced as follows: About 250 c.c. or more of the urine, as freshly voided as possible, are poured into a glass percolator, such as are used by druggists in making tinctures and fluid extracts. The cylindric or Oldberg form is to be preferred, as the sediment collects more completely at the bottom than when using the conical form. The opening at the bottom of the percolator is closed with a perforated rubber or cork stopper through which passes a piece of glass tubing about 4 centimeters long, and this is connected with a short piece of pure rubber tubing provided with a pinch cock. The entire apparatus, before pouring the urine in, should be washed thoroughly clean and sterilized by the application for a sufficient length of time of a suitable germicidal agent, such as a dilute solution of formaldehyde, followed by washing with recently boiled water. After pouring in the urine a gram or two of chloral hydrate, dissolved in a few cubic centimeters of warm distilled water, are added to retard decomposition; the percolator is now covered with a glass plate and set aside in a cool place for eighteen or twenty-four hours. At the end of this time the sediment of the urine will be found in the bottom of the percolator; if the urine is from a case of suspected interstitial nephritis, for which this method is particularly adapted, the deposit will usually be a light flocculent cloud, and sometimes instead of being at the very bottom of the percolator it will be found floating a few centimeters above it. By opening the pinch cock on the rubber tubing the sediment is drawn off and collected in one or two centrifuging tubes; in all cases the first cubic centi-

meter or two may be rejected as it contains little or none of the sediment, and in case the deposit, as spoken of above, floats somewhat above the bottom of the percolator, enough of the urine should be slowly drawn off to bring the deposit down to the outlet before collecting in the centrifuge tubes. The latter, which now contain in 20 or 25 c.c. practically all the sediment from the original 250 c.c. or more of urine, are placed in the centrifuge and submitted for a few minutes to about 3,000 revolutions a minute. By this treatment the sediment is condensed to a small deposit at the apex of one or two tubes, from which it is removed by a pipette and examined under the microscope. With suitable care essentially the entire sediment from 250 c.c., or even 500 c.c., of urine from the average patient with suspected cirrhosis of the kidney, may by this procedure be reduced to from one to four small drops within which, it is evident, are practically all the casts of the large volume of urine employed. The work of examining this small volume of sediment under the microscope is usually brief. If casts are present in sufficient number to be of clinical significance they are generally found quickly.

If, as just described, the percolator is sterile and sufficient chloral hydrate has been added to the urine, the latter generally undergoes during the 18 to 24 hours of its subsidence only a slight change, and this instead of being a detriment is undoubtedly of considerable advantage for the purpose in view. The change referred to is the coagulation in a very light, flocculent state of a part of the mucin of the urine which in settling out unquestionably collects and carries down with it any casts that may be present, acting very much as the white of an egg does in clarifying or "settling" turbid coffee.

Instead of a percolator, as directed above, a tall glass cylinder or bottle may be used, the sediment being drawn off at the end of 18 to 24 hours by means of a pipette and transferred to centrifuging tubes. A percolator, however, or some other similar device is considerably to be preferred, the deposit from the urine being much more perfectly collected and easily drawn off in its entirety than by the other method.

If we wish to stain the casts or other sediment the appropriate dye may be added to the liquid in the centrifuge tubes before centrifuging, and in a like manner chemical reagents, such as acetic acid to clear up phosphates, may sometimes be used to advantage.

To the conscientious physician who has not infrequently devoted many long sittings to examining under the microscope, often with negative or questionable results, the sediment (whether obtained by gravity or centrifuging) from repeated samples of urine from a patient suspected of having incipient cirrhosis of the kidney, the method just described will be, if our experience is any criterion, a most welcome change. It is true that eighteen to twenty-four hours must elapse after receiving the urine before results may be obtained; but these hours involve no labor and when, at their close, the drop or two of ultimate sediment are placed under the microscope their examination in the great majority of cases may be made with at least comparative ease and rapidity, and with a confidence in the results, even if they are negative, that is in very gratifying contrast to the uncertainty often following the previous laborious methods.

The following test shows the superior ease and ac-

curacy of this method of detecting casts. A sample of urine was secured that was known to contain a very few casts: it was divided into three parts, one of which was submitted to the centrifugal, another to the gravity, and the third to the present described combined process. Although the sediment obtained in the centrifuge was examined with exhaustive care no casts were found; an equally painstaking examination of the gravity deposit revealed a single cast; with the combined process, however, four or five casts were easily found in the first slide placed under the microscope and with an expenditure of time not one quarter as great as that given to either of the other two examinations.

We give only one of the several cases that have recently come under our observation illustrating the clinical value of this method of searching for casts.

Mr. X., 58 years of age, robust physique, a gentleman of means, and assiduously engaged in many commercial enterprises; a good liver, but temperate in the use of tobacco and alcohol; has never had any very serious sickness; family history good, although one and possibly two brothers are believed to have died with Bright's disease. He has had many persistent neuralgic attacks in different parts of his body and has suffered from frequent backache. There is slight enlargement of the left ventricle with moderate increase in arterial tension. The urine is of light color, averages 1,500 c. c., specific gravity about 1.017, slight increase of total acidity; upon standing, only a little light sediment is as a rule thrown down. For two or three years both he and his family physician have feared some organic kidney trouble and as a consequence he has consulted a number of doctors making more or less of a specialty of these disorders. They have all examined his urine and he has preserved their written reports. All have found minute traces of albumin at times, but only one has been able to find casts, and he after long and repeated search had discovered only two. The various physicians differed in their diagnoses, most of them, however, believing that, in the entire absence of casts, organic kidney trouble did not exist, or at least could not be demonstrated. During the past few months the gentleman has been repeatedly under our observation. His urine has been examined microscopically by us several times, using both the gravity and centrifugal methods of getting the sediment, with negative results except on one occasion when by the use of the centrifuge a single hyaline cast was discovered. Upon applying the present combined method, however, we have never failed to find, even with only a moderate amount of search, from two to five casts and sometimes even more. This in conjunction with the other features presented by the case makes the diagnosis certain.

It is evident that this method, while designed especially for detecting casts, may be used with great advantage in examining for any other sediment in the urine, and we have not infrequently employed it in searching for spermatozoa, epithelial cells, micro-organisms, etc., especially when these elements were sparingly present.

In conclusion we should say that, singular as it may seem, the chief defect for clinical purposes in the present method is possibly its too great delicacy. By its use we have found that if sufficient time and care be given to the microscopic examination casts may be found in the majority of samples of urine even

from persons in perfect health. Our observations on this important subject are not yet quite complete, but before long we shall publish our results.

A NEW AND SIMPLE METHOD OF OBTAINING THE URINE SEPARATELY FROM THE TWO KIDNEYS IN EITHER SEX.

Read before the Chicago Medical Society, Jan. 12, 1897.

BY M. L. HARRIS, M.D.

PROFESSOR OF SURGERY, CHICAGO POLICLINIC.
CHICAGO, ILL.

Owing to the vital importance of the renal function the desirability of being able to determine the presence or absence of a kidney, as well as its functional capacity, has long been recognized by every surgeon who has been called upon to remove one of these organs for some incurable disease. It is a well-known fact that, owing to an error or arrest of development, an individual may be possessed of but a single kidney, or one of the kidneys may be so atrophied or misformed as to possess but little, if any, functional activity. It has more than once been found at the autopsy that the kidney removed by the surgeon was the only one possessed by the patient.

While absence of a kidney is quite rare, being found in only one out of about thirty-three hundred cases (Morris) or 0.03 per cent., still where but a single kidney exists, it is much more liable to become diseased.

In De Jong's (quoted by Wagner, *Deutsch. Zeit. f. Chir.*, 24, 581) collection of 197 cases of nephrectomy with 81 deaths, in 2, or nearly 2.5 per cent. of the 81 deaths, the other kidney was found to be absent, while in 9 it was so atrophied or diseased as to be practically functionless. Thus in 11, or 13.5 per cent., death could have been avoided, or at least not directly charged to the surgical operation, could the condition of the opposite kidney have been determined beforehand. Much thought and ingenuity has been expended in devising ways and means for determining the presence or absence of a kidney. It is quite universally acknowledged that physical examination by palpation, percussion, etc., is absolutely unreliable under ordinary circumstances in determining the presence of a normal kidney, normally located. Hence, attention was early directed in the line of securing the urine separately from the two kidneys. Could this be done with certainty it would not only establish absolutely the presence of two kidneys (except in a few rare anomalies of development), but would be of very great service from a diagnostic point. Even when it is quite certain that the kidney is diseased it is often impossible to determine from the symptoms and a physical examination which kidney is at fault. To be able to collect the urine separately from the kidneys is thus of inestimable diagnostic value.

It is unnecessary to describe in detail the various methods and appliances that have been devised to accomplish this object, still in presenting anything which is claimed as new and original it is well to mention what has preceded in the same line.

We may mention first Simon's suggestion of compressing the ureter at the brim of the pelvis with the hand introduced into the rectum. On account of the great difficulty and danger of introducing the whole hand into the rectum, it was substituted by Davy's rectal lever as in compressing the common iliac artery to control hemorrhage. Following this appeared num-

erous forceps or compressors for shutting off or closing one ureter temporarily while urine escaped from the opposite one. To this class belongs Tuchman's forceps, shaped like a lithotrite. With it one was supposed to be able to feel the ureteral orifice in the bladder and compress it in the jaws of the forceps.

Ebermann's forceps for compressing the ureter with one blade in the bladder and the other in the rectum. Polk's S-shaped catheter for compressing the ureter against the finger in the rectum. Müller's curved spring pad introduced into the rectum. Silbermann's rubber bag introduced into the bladder and filled with mercury so as to compress the ureter on one side.

Some of these compression instruments were visionary, while all of them were so unreliable as to be of no practical value. Next we may mention Hegar's and Säger's method of cutting down upon the ureter in the anterior vaginal fornix and temporarily compressing it with a ligature, and Warkalla's "umstec-kungs" method.

Attention was now directed to the ureteral openings and Pawlick with a delicacy of touch and manipulation that has not been equaled by anyone else, has repeatedly been able to catheterize the ureters of the female through the urethra by touch alone.

Fenwick devised a curved catheter with a large lateral opening, which he hoped to be able to place over the opening of the ureter, and thus by means of a rubber bulb suck the urine directly from the ureter. Considerable light was now thrown upon the subject by the appearance in the field of a number of cystoscopes after the Nitze-Leiter plan by the aid of which the ureters have been successfully catheterized. They are so complicated, however, and require so much practice and dexterity to use them successfully as to be practically beyond the ordinary practitioner.

Simon devised a female urethral speculum through which by means of a reflector or electric headlight the interior of the bladder could be seen as it became distended with air and the ureters thus catheterized by sight. Kelly improved and popularized this method, and following his directions many operators have been able to catheterize the female ureters.

It is however no simple thing, but requires considerable practice, great patience and dexterity, and I have seen those experienced in the method obliged to give up after many minutes of fruitless endeavor. It is likewise at times so painful to the patient as to require an anesthetic, and repeated unsuccessful attempts to enter the ureter may cause a hemorrhage which may seriously interfere with the object in view.

Numerous operators have resorted to suprapubic and perineal cystotomy in the male and vesico-vaginal fistula in the female in order to catheterize the ureters.

Two quite recent methods which do not have in view the catheterization of the ureters deserve mention. Rose (*Centralbl. f. Gyn.*, 1897, Nos. 5 and 21) uses an urethral speculum similar to Simon's and Kelly's, the inner end of which is cut obliquely or on the bias.

The idea is to cover the ureteral opening in the bladder with the end of the speculum so the urine will flow directly into the speculum, from which it can be secured. He admits that this is at times very difficult to do and other methods may have to be tried.

Neumann (*Deutsch. Med. Woch.*, 1897, No. 43) describes a large-sized catheter-like instrument with a septum extending longitudinally throughout its entire length. The septum extends beyond the inner

end of the tubes, which open respectively one on either side. When introduced, it is intended the septum should lie snugly against the posterior wall of the bladder, aided by the finger in the vagina, so as to form a water-tight partition and thus guide the urine from each side into the respective side of the catheter. Rose (*Deutsch. Med. Woch.*, 1897, No. 48) criticised Neumann's instrument and showed the unreliability of his method.

Nearly all the preceding devices have been applicable only to the female, the male being practically out of the question.

The great difficulties and unreliability of the methods proposed have led such practical surgeons as Czerny and Israel to establish renal and ureteral fistulae

an arc of about 60 degrees of a circle, with a radius of 35 mm.

This curved portion does not pass at once into the straight portion, but is set on a slight forward angular displacement about 3 or 4 mm. in length. Upon transverse section this curved portion is approximately a semicircle, so that when the flattened surface of the two catheters are opposed it is nearly round. Near the end on the flattened surfaces and the lateral portions of the semicircular surfaces are three or four small perforations. The distal extremity of each catheter is round and curved in the same plane as the proximal extremity, forming about the quadrant of a circle, the same as the curved end of an ordinary male sound. (Fig. 1.)

FIGURE 1.

FIGURE 2.

in the lumbar region in order to decide which organ is the seat of disease, and such men as Thornton, Morris, Fenger and others to perform preliminary ventral celiotomy and bilateral lumbar incisions, in order to permit palpation of the kidneys.

The above does not contain all the slight modifications which have been proposed, but illustrates all of the principles thus far brought out. With this brief introduction then, we may proceed to a description of our own device and the method of its application.

The instrument although quite simple is, as usual, somewhat difficult to clearly describe. It consists of

FIGURE 3.

a double catheter, each being separate throughout, but both being enclosed in a common sheath throughout its shaft or straight portion, thus giving it the appearance of a single tube flattened from before backward. Each catheter, however, is separately movable about its longitudinal axis within the sheath. The sheath, or longitudinal straight portion of the catheters, is 20 cm. in length, graduated in centimeters along its upper surface. A detachable handle is attached to the longitudinal portion. The proximal extremity (in reference to the patient) is curved somewhat similar to an ordinary male sound—forming

The curves of the two extremities being in the same plane, the distal end will always indicate accurately the exact direction of the proximal end. At about the junction of the distal curved with the straight portion is a short tube, continued in the line of the straight portion and opening into it. The distal extremity of each catheter is connected by means of a short piece of rubber tubing with a separate glass vial. The corks of the vials are doubly perforated. Each vial is finally connected by means of a piece of rubber tubing with a single rubber exhaust bulb. (Fig. 2) As part of the device there is a metal

lever about 25 cm. in length, with a handle at one end, the opposite extremity being suitably curved and flattened laterally. (Fig. 3.)

The instrument is used in the following manner: The patient, male or female, is placed comfortably on a table in the ordinary lithotomy position, with the hips slightly elevated. The instrument, with the flattened surfaces in contact so as to form practically a single catheter, is introduced into the bladder in the ordinary way. So soon as the proximal curved extremity is within the bladder, the proper distance being indicated by the graduated scale, each catheter is rotated about its longitudinal axis until each proximal end, as indicated by the distal end, is directed outward and backward. The end of each catheter should pass through an arch of about 110 to 120 degrees, or so that the angle subtended posteriorly by the two catheters will be about 120 or 140 degrees. They are held in this position by a small spiral spring. The ends of the proximal extremity will now be in the neighborhood of, but not exactly at, the ureteral openings. The ends are separated a greater distance than the distance between the ureteral openings so as to avoid the danger of compressing the opening of the ureter, and thus preventing the escape of the urine. The lever is now introduced into the vagina in the female or rectum in the male. By gentle pressure forward directly in the midline, the base of the bladder is raised into a longitudinal fold between the ureteral openings.

The curve of the lever is such that it fits nicely in the angle formed by the separating extremities of the catheters, thus forming a complete watershed. The end of each catheter now lies at the most dependent part of a little pocket, a perfect watershed separating the two. The ureters open, one on either side of the watershed near the base of the declivity in the immediate vicinity of the respective end of the catheter.

By producing a gentle exhaustion of the air in the vials by means of the bulb, the urine, as fast as it escapes from the ureters, drops directly into the ends of the catheters and flows at once into the vials, right and left respectively.

The instrument and its application are so simple that its advantages are apparent at once, and hence need no arguments to support them.

This being the case, we may proceed at once to dispose of any possible objections that may suggest themselves.

The first question which naturally suggests itself is, is the watershed perfect and complete so that there can be no intermixture of the urine escaping from the opposite ureters? My first experiment was made on the cadaver. A supra-pubic cystotomy was made on a male cadaver, so as to thoroughly expose the interior of the bladder to view. The end of the rubber tube of an ordinary irrigator was inserted into the upper end of one of the ureters. The watershed was now made by the lever introduced into the rectum and the water from the irrigator allowed to slowly flow into the bladder. It would flow at once to the inner end of the catheter on that side without leakage to the opposite side.

Through the kindness of Dr. C. E. Manierre, I had an opportunity of using the instrument on one of his patients, which afforded an absolute demonstration of the completeness of the watershed. It was a female, from whom he had removed the right kidney about a year previous; hence, no urine could possibly

enter the bladder except through the left ureter. Although the instrument was used several minutes and considerable urine collected in the left vial, the right vial remained perfectly dry, not a drop of urine appearing in it. We must conclude from this that the septum or watershed is perfect.

The possibility of compressing the opening of the ureter and thus preventing the escape of the urine from that side is obviated, as already mentioned.

In diseased conditions of the vesical mucosa the value of an examination may, upon first thought, appear to be considerably lessened, owing to contamination of the urine with products of vesical origin. Upon reflection, however, this will be found not so. The bladder, when necessary, should be thoroughly cleansed by irrigation before introducing the instrument. After the instrument is in place the little pockets may be again cleansed by irrigating them directly through the little straight tubes on the distal end of the instrument provided for that purpose.

The urine as fast as it escapes from the ureters is sucked at once into the catheters, so that it does not remain in contact with the mucosa. The end of the catheter is so near the opening of the ureter that the urine comes in contact with an extremely small portion of the bladder surface. The examination is not continued long enough at any one time for pus (for instance) to be formed in sufficient quantity to be taken up by the catheter. Hence it will be seen that contamination, even when the bladder is diseased will be slight.

It is likely that in certain greatly enlarged prostates or growths of the so-called middle lobe or in vesical calculi or chronically inflamed and contracted bladders, the instrument would not be applicable, but such cases form a very small minority of those in which its use would be desirable.

A few words in regard to the use of the instrument. The little straight tubes, when not being used for irrigation, must of course be closed air tight by simply tying the little rubber tubes attached to them, or passing the opposite ends of a single tube over each straight end. Aspiration with the bulb should not be too great so as to draw the mucosa into openings of the catheter. Very slight aspiration is all that is necessary. As a few drops of fluid are apt to remain in the bladder even after the use of a catheter, the first few drops that come over should be discarded.

The instrument should be opened carefully when in the bladder, so as not to excite hemorrhage by injuring the mucosa. The proximal curve should be just within the bladder, which is determined by noting the length of the urethra on the scale. Introduce the instrument into the bladder and open it before introducing the lever into the vagina or rectum. The ends of the catheters are easily felt through the vagina or rectum, and the lever should be directly in the midline, midway between the two ends and pressed snugly into the angle. Sufficient pressure should not be used to cause pain, as the watershed is very easily formed. The urine does not drop continually into the vials but intermittently, just as it escapes from the ureters. The use of the instrument is not painful and does not require an anesthetic, except possibly in an oversensitive or nervous patient, who would not submit to any manipulation whatsoever.

By attention to these simple rules the application of the instrument will be found very simple, and the results all that could be desired.

FEEDING OF SURGICAL PATIENTS.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY ALBERT H. TUTTLE, S.B., M.D.
CAMBRIDGE, MASS.

Certain special considerations in regard to the feeding of surgical patients have induced me to take up this subject for discussion, that is, the need of definite instruction which will enable the nurse to practically comprehend the requirements of her patient and the simplification of the food materials employed. The subject is naturally divided into three periods, viz.: Before operation; after operation up to the time that the bowels are established, or the immediate effects of the anesthetic are eliminated and finally the period of convalescence.

The first period is of variable length from a few hours to days or even weeks, depending upon the condition of the patient, the severity of the disease and operation and the necessary amount of preliminary preparation required. During the first period it is the aim of the surgeon to build up the strength and resistance power of his patient and, just before the operation, to prepare the bowels by emptying them as completely as possible. Unless we have been careful about the preliminary treatment it will be difficult to completely clear the bowels without exhausting the strength of the patient, owing to the fact that the bowels are affected by the nervous condition of the patient, which is generally present and perhaps has existed for a long period. In my experience most female surgical patients suffer from enervation of gastro-intestinal tract, with constipation, mal-assimilation and imperfect nutrition as a result of this weakness of the nervous system. Before a severe operation this should be overcome by toning up the patient as much as possible by overfeeding and tonics. The more severe the operation the more important it is that the bowels should be satisfactorily cleared of all the fecal matter and, at the same time, every effort should be made to support the patient and guard against subsequent shock. In order that we shall accomplish this we must feed the patient for some time before the operation on an efficient diet, yet one which will leave as little residue as possible for removal by catharsis. I believe that during this period we should use liquid foods which consist of a combination of nitrogenous and vegetable substances. Milk alone and combined with eggs, sugar and liquor, form one of the best nitrogenous preparations we have at our disposal, and another is beef juice prepared as follows: Thick, juicy meat from the bottom of the round is cut into slices an inch or more thick. This is heated in a slightly buttered, hot spider, so as to rapidly sear both surfaces and warm the meat completely. (This starts the juices and is very essential to success.) The slices are now cut up into cubes or strips and squeezed in a meat press which has been previously warmed in hot water, until all the juice is extracted. The juice should be collected in a warm vessel, salted and seasoned to taste and administered while it is still warm.¹ I have found that many patients prefer to take the juice in port wine that has previously been diluted with water. The number of patients who dislike either of these preparations are

very few, which is more than I can say of any of the nitrogenous prepared foods on the market. They also offer the advantages of fresh preparation and lower costs. The meat juice to a certain extent acts as an iron tonic owing to the amount of hemoglobin which it contains. For the vegetables constituents of the diet I have depended upon barley, oats, flour, rice and corn meal prepared in the form of gruels and strained before ingestion. The fluid foods should be given at regular intervals of two hours from 6 A.M. to 8 P.M. and in a variable quantity, according to the demands of the patient. Coffee, tea or chocolate are given in small quantities only or completely withheld. Liquid malt is a valuable adjunct, aiding digestion and assimilation and in a measure serving as a pleasant bitter tonic. In certain cases an occasional dose of malt and cascara are of value in assisting the action of the bowels. The triple bromids in doses of 6 grains, t. i. d., act as a sedative to the nervous system as well as a bland aperient and indirectly help in the feeding of the patient. It sometimes happens that a patient can not bear liquid food well as it induces gaseous and acid fermentations with symptoms of abdominal distress. In these cases a carefully selected diet of solid or soft-solid food may be substituted during the preliminary treatment and until the day previous to the operation. On this day liquid food only should be given and on the day of operation all food should be withheld. Some surgeons are in the habit of giving their patients a bowl of clear soup early in the morning of the operation, but I prefer to substitute for this a cup of strong coffee. With careful attention to the above details the bowels can be easily moved or will act spontaneously at least once daily as a rule. If in obstinate cases they fail to do so, a mild aperient will produce a satisfactory evacuation. The result is that just preceding the operation the bowels can be efficiently cleared without upsetting the patient, by the administration of a small dose of castor oil during the evening before, and by washing out the lower bowels with soapsuds early on the morning of the operation. Formerly it was my practice to administer calomel and follow this up with salts, but I found it upset the patient, often caused many unnecessary discharges of a watery and depressing nature and, unless given in large doses, was uncertain. If the calomel is not entirely eliminated there is danger of some subsequent salivation and stomatitis. Patients do not complain of the bad taste of the oil if it is covered up with coffee or the oil is given in the form of an emulsion. After an operation all food should be withheld for a certain length of time. In the simplest class of cases patients feel better if they eat nothing until the following morning, and in abdominal cases it is absolutely necessary to maintain total abstinence for one or more days. In abdominal cases it should be the rule not to feed by the mouth until the normal peristaltic action of the bowels is fairly well established. This is marked by the passage of flatus per rectum and the flatness and softness of the abdominal wall. This rule should be imperative and, no matter how long it may take to establish the bowels, should be carefully followed. It is well to remember that by rectal feeding one often helps the bowels by starting peristalsis from below upward and in the normal direction. The first food after the administration of an anesthetic should be of a bland nature and of a limited amount. Three to four ounces of gruel or a few crackers with

¹ The Enterprise Manufacturing Company have placed upon the market a meat-juice extractor which is modified from their meat chopper and which gives very satisfactory results.

black coffee are well borne. Malted milk and Mellin's food are sometimes preferred; their peculiar flavors seem to suit the taste of certain individuals. If the patient is suffering much from enervation of the gastro-intestinal tract before the operation, liquid food with occasionally a cracker or piece of dry toast will often be tolerated when more substantial food would cause distress. If the operation has been one of abdominal section, then the first feeding should be per rectum and peptonized milk and gruel in one-half pint quantities are given at the intervals of five to eight hours. This is first employed at the end of the second or third day, according to the case, and is continued from one to three or more days, until the bowels are free from gas and distension and the passage of flatus from time to time indicates the establishment of normal peristalsis. Simple cases rapidly advance toward the natural condition and in the course of twenty-four to forty-eight hours become fit for the feeding of the third period. The abdominal and cases with nervous depression are less rapid and suffer from distension and symptoms of distress with the slightest excess of food. The use of malted and peptonized foods in these cases should be persisted in for several days. After they become inefficient the patient feels a desire for more substantial food and the bowels are usually active with a daily dejection, or at least one every other day. At this stage a meal of soft solids can be given at midday, consisting of eggs, oysters, custards, rice, tapioca, bread pudding, blanc mange or the various oat, barley or wheat mushes. At the end of a couple of days, with this feeding, meat and potatoes can be added to the main meal of the day, and mush, eggs, toast and fish can be given for breakfast. By the end of a week from the time the patient has begun the taking of solid food, three regular meals can be given daily. It is better, however, to withhold meat from that of the evening.

The third period is characterized by house diet three times a day and such extra feeding as may be specially indicated by the condition of the patient. Three regular meals a day and two or three lunches are usually prescribed. Breakfast consists of mush, hot bread or gems (made from whole wheat, corn meal or flour), broiled chops, steak, fresh fish or eggs, with chocolate or coffee. Dinner comprises soup, a roast of meat (lamb, beef, chicken, game, turkey), fish, potatoes, green vegetables, bread and pudding (custard, bread, tapioca, rice, etc.). Supper is made of bread, toast, oysters, cold meat, hot gems, cold custard, blanc mange, assorted crackers, with tea or chocolate. All sweets, as candy and preserves, should be withheld and fruits allowed only in limited quantities. Cake and pastry and all articles cooked in fat are also prohibited. Lunches are served two and a half hours after each regular meal and consist of milk, eggs and crackers. By careful feeding in the above manner a large amount of food may be taken, digested and assimilated daily, and at no time will the stomach become over-distended.

If symptoms of distress from gaseous or acid fermentation occur, the regular feeding is suspended for a few hours and the condition corrected by the administration of bismuth and salol and sometimes in urgent cases, a small dose of morphin (one-sixteenth of a grain) is given, which controls the discomfort and nervous state of the patient better than anything I have hitherto tried. Every effort should be made to vary as much as possible the diet of each day. A

careful study of the patient will often reveal some idiosyncrasy or special weakness in the digestion of particular food. Whenever a patient expresses herself as unable to eat certain things without a great deal of subsequent discomfort, I believe it is wise to respect this opinion and withhold the food complained of for the effect on the mental condition, if nothing more.

DISCUSSION.

The Secretary, Dr. EPHRAIM CUTTER of New York, remarked that the title of this paper included the feeding of surgical patients so as to do away with surgical operations. For example, some years ago a man was brought to him with chronic pleurisy and empyema. A fistula had discharged pus for four years. It had been proposed to resect the ribs as a last resort. This case entirely recovered in a few months by feeding only. Another case of the same kind came under the care of the speaker a few years ago but in a female and of less years standing. It was permanently cured in two months' time by feeding. The diet in both these cases was one pint of hot water before meals and on going to bed, and beef broiled after removing the white fibrous or glue tissue, which glue tissue ferments as sugar does in the alimentary canal. Two mouthfuls of broiled beef to one mouthful of vegetable food (*i. e.*, bread made from the Franklin Mills entire wheat flour) were thus proportionately eaten. A bad case of frog felon came into the hands of a surgeon who cut, but said the man would die as it was very severe. He was right, had the feeding been conventional. But the writer, called in consultation, advised large porterhouse steaks thrice a day as medicine. The man made a fine recovery. Perhaps some may say that these are not germane. Let me then give another case. Some twenty years ago a lady dieted for a round fibroid about three inches in diameter, sessile, on the fundus of the uterus. She tired of the slow process and T. Gaillard Thomas, M.D., LL.D., removed it by the knife. I saw the case during the convalescence. Dr. T. assured us that he never had a case do so well. While I think that the writer is right I should like it much better if people would feed so that no surgical operations would be necessary, but as man now is, this is too much to be hoped for.

WHAT THE MEXICANS EAT AND DRINK.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY F. SEMELEDER, M.D.

CORDOBA, STATE OF VERA CRUZ, MEXICO.

At the time of the conquest, Mexico was very poor in vegetable and animal food. The people consequently had to make up for the different things they lacked and eat certain indigenous animals and plants, some of which a European would hardly think of tasting, unless compelled to it by the most extreme hunger.

Wealthy people eat as do the same class in Europe, but their table will always show some national dishes, and in the most fashionable houses pulque will be found on the table.

In dedicating these lines to the especial Mexican dishes it will be understood that we refer to the Indians and the poorer class of people, their food is mostly vegetable. The basis of it is Indian corn in different forms, from the green and half ripe ear to the grits and flour.

Half of the food of the Mexicans consists of *tortillas*. The corn is soaked in hot water with a little lime. In that state it is called *nixtamal*. Then it is ground on a flat stone (*metate*) with a stone roller (*metlapil*) and reduced to a thick mass, out of which the flat, thin cakes, called in Spanish *tortillas*, and *tlaxcales* in Nahuatl, are formed with the hands and baked on a flat dish (*comal*) over the fire. To make *tortillas* is the business of the women and takes most of their time. In order to avoid this and enable the

women to do other work, mills have been set up to grind the corn, but in general the country people do not like the tortillas made by this process. It is certainly a great economic drawback that almost the whole time of the women of the poor should be required to make their tortillas, instead of employing themselves in some other profitable work. When the corn is boiled they make with lard, butter, red pepper, sweets or meat, a kind of rolls, enveloped in corn husks and boiled. These are the *tamales*. In the north and in certain parts of the coast the Indians mix corn flour with brown sugar. This mixture is called *pinole*. With a small bag of that an Indian will work and travel several days.

Another necessity of the Mexican is red and green pepper, which is used to season every dish. A Mexican meal is not complete without a dish of *frijoles*, beans. The Mexican can hardly do without chocolate and, if he can afford it, he will take it in the morning and in the afternoon or at night; it is always flavored with cinnamon.

The Mexican is not a great eater, nor can he be called an epicure. The hot taste of the red pepper seems to dull his palate and render him unable to appreciate the refinements of gastronomy. Salt is scarce and dear and little used; for the Indian a pinch of white salt is a great luxury. The indigenous vegetables are many and we can only enumerate a few: The sprouts of a *Smilacina*, eaten like asparagus; the buds and flower of the palm *Chamaedorea tepejilote* (called *metepehuiles*), the sprout of a large palm which is eaten like cabbage; the young and tender leaves of the *Opuntia* (nopal, prickly pear) called *nopalitos*, the leaves of a *Piperacea*, *tlahnepaquelitl*; the flower of the *Yucca gloriosa*; the gombo, *Hibiscus gombo*; the flowers of a *Papilionacea*, *Erythrina coralloides*, called *quimites* and *gasparitos*; the red and green pepper (*Capsicum annuum*); tomatoes, red and green (*Lycopersicum* and other solaneas); the pumpkin, when young and tender or when fully developed; the pumpkin flower; melon and watermelon (introduced from Europe); the flower of the *quauzontle* (blitus bonus Henricus). In the northern states the prickly-pear (*tuna* in Spanish) forms a great item in the subsistence of poor people. To season dishes they use *epazotl* (chenopodium ambrosioides) and *papaloquelitl* (porophyllum coloratum, D. C.), the *Amaranthus hypochondriacus* (quintonil). The chenopodium viride (*quelitl*), the *romeritos*, the marshmallow, the purslane (portulaca), the *roconoxtli* (literally red berry), the sour tasting fruit of a certain cactus. The *mohitli* (sericographis mohitli), *tè limon* (Andropogon citratus, D. C.) *tè de milpa* (bidsens tetragonum) and orange leaves in infusion are common beverages taken in the morning with or without milk. Fish and amphibia: Of the latter the iguana (cyclura and iguana), lizards which are sometimes three feet long, in the warm lands; turtles and their eggs. In the lakes of the tableland the white fish (*Atherina Humboldtii*), the *juil* (*Cyprinus Americanus*), the *mertlapique*, a viviparous small fish; the *axolotl* (various classes of *Amblystoma*) which was only lately found to develop into a lizard; a kind of clam (*almeja*, a strange derivation from *mytilus*, *Anodonta Mexicana*); a small kind of fresh water shrimp, about one inch long, *acaucil* (*Cambarus Moctezumae*). In the rivers along the coast crawfish is found, but rarely; also eels and shad. A small kind of snipe (*chichicuilotes*) living in great numbers on the marshes of the valley of

Mexico; ducks when they pass through on their passage north and south. *Ahuautle*, the roe of a kind of fly of the hemipterous family, *coryza femorata*; the locust, when it appears on the coast; the *rumil*, in the south, with a peculiar odor like bugs; the chrysalis of a night butterfly, living in the maguey plant; a kind of caterpillar, over an inch long, with black hair, living in nests on trees, etc. Of quadrupeds: In the warm lands, the armadillo and a kind of opossum.

What the Mexicans drink: Water, first of all, though even that in many places is rare, bad and unwholesome.

Putque, the national drink, called the "Mexican wine." We shall have to devote a special chapter to the plant that yields pulque and to the process by which it is prepared. In this place we consider pulque only as a drink. It comes from the northern parts of the States of Puebla and Mexico, along the Vera Cruz railway. The maguey plant grows on soil where nothing else can be produced and, as the pulque has a ready sale at a profitable price, the cultivation constitutes the special wealth of all this part of the country. Pulque is consumed in large quantities; the Vera Cruz railroad runs a train every night to carry it down from Apam, to be distributed in the City of Mexico in the early morning. The railway freight for pulque is on an average \$1,000 a day. Pulque is a white liquid, with dregs of slimy flocks, of sour taste and smell, with a putrid flavor. Besides the alcoholic and acetic, likewise putrid fermentation is going on; the latter explaining why pulque can not be preserved, as it continues fermenting until the whole liquid is spoiled. It is drunk two or three days after being made while it is yet fermenting, and is adulterated, as is everything that is extensively used. Pulque is alcoholic and highly intoxicating; as it is very cheap it ought to be the delight of drunkards; for one cent you can get a big tumbler full and for two or three cents a man can drink himself beastly drunk. The common people in Mexico are great drunkards. It is said to have digestive and nutritive properties; but this can not be true, for nowhere in the world do you find more anemics and with poorer digestion. For festivals pulque is cured with different classes of fruit. Some years ago a speculative fellow tried to export preserved pulque. An advertisement has been sent to us, with the information that somewhere in Jersey City genuine preserved pulque can be had. The advertisement contributed to it every good quality and went far enough to say: "Pulque, notwithstanding the alcohol it contains, never produces the bad effects of alcoholism, even when taken in excess." That is humbug. Pulque can not be preserved. When fermentation is artificially interrupted, the liquid is no longer pulque. An inferior class of pulque is called *flachique*. The sap of other kinds of agave furnishes a fine brandy called *mexcal*, which has a smoky flavor, much like Scotch whisky. The brandy made at a certain hacienda in Jalisco takes the name of the place: Tequila.

Cheap brandy, *aguardiente*, burning water, is made in sugar factories and called *chinguirite*. A certain class of brandy supposed to come from Spain and to be made of grapes, is called *catalan*.

Colonche.—In the interior of the country where the Agave will not grow, an alcoholic drink is made from the juice of the red tuna (prickly-pear). By adding water and brown sugar, the juice is made fit for alcoholic fermentation. To make it stronger and more

durable, brandy is added. It is quite intoxicating.

Beer of good quality and high price of late is extensively made in the country.

Wine.—The cultivation of the grape was prohibited by the Spanish rule in order to monopolize the sale of wine for Spain. Now grape is cultivated in different parts of the Republic. In the central and lower lands it does not yield well, for the rainy season begins just when the grapes need dryness and heat. The same circumstance prevents the culture of hops. The places where wine is best grown are Dolores (State of Guanajuato), Parras and other places in the State of Coahuila. Genuine and good Mexican wine, like an inferior class of sherry, can be had in the City of Mexico for twenty-five cents a bottle. As it is not appreciated and finds no sale, all that wine goes to Texas. Certain extensive plantations in Coahuila, where good care is taken of the grape, produce a first-class quality, equal to the better classes of Spanish and Greek wines. By adding large quantities of sugar, the juice of oranges can be made to ferment into a kind of cider.

Chia.—The seed of a species of sage (*salvia chian*) a small black grain, when kept in water for some time covers itself with a grayish, slimy layer and looks then very much like frog-spawn; it is diluted with water, sweetened and flavored with the juice of certain classes of fruit and makes a nice refreshing drink.

Chicha is made by boiling barley; then the water and barley is exposed to the sun and air for a few days; when it begins to ferment it is sweetened and mixed with pineapple juice and is then a cooling beverage.

Tepache.—Dregs of pulque or toasted barley or crushed sugar-cane form the basis; mixed with water, pineapples, bananas, guayabas and sugar it is put to ferment; then nutmeg, clover or cinnamon is added, as well as molasses, and the liquor is ready. It is alcoholic.

Tibico.—When sugar-cane in the factories has gone through the cylinders the remains fall into a tub; the larger fibers are taken away to make brandy; the smaller ones like bran, remain a few days in the tub, fermentation begins and a kind of microscopic fungus develops. In this state it is called tibico; that is taken out and beaten with water, which causes an enormous and rapid growth of the fungi, so that the liquid increases under your eye. It is then diluted with water, sweetened with brown sugar, flavored and drunk. Hence tibico has become the synonym for exuberance.

A great comfort in hot countries is a refreshing drink. Plenty of natural ice is obtained from the volcanoes, and lately in several places artificial ice is to be had. In all the other places of the country, to get a cool drink of water, porous clay jars are used; by the constant oozing and evaporation of the water on the surface the contents of the jar are kept cool. In many places of the hot lands you see these jars hanging from the roof in the hall or in the corridor of the house and whoever feels like it helps himself to a drink.

Tuba.—On the Pacific Coast there grows a kind of coco-palm, not known on the Gulf Coast. The nut is of the size of a child's head, the flesh abundant and soft, so as to be eaten with a spoon. When the bud comes out, before the flower is developed the bud is cut off and a milky, very sweet sap distills out, which is drunk fresh or after fermentation. This is in Col-

ima the drink of the poor people and is called tuba.

The lowest class of Mexicans have always been great drunkards. Pulque has a disastrous effect on the body and mind, but not quite so bad perhaps as common brandy. The Mexicans of the better classes were formerly exceedingly sober; twenty-five years ago there were not more than half a dozen cantinas in the City of Mexico; now there is one at nearly every corner. Drunkenness is now a common vice with young men of good families; they consider themselves more like men and equal to the Americans if they indulge in excessive drinking. Older people drink hardly anything but water; wine is very dear on account of the heavy duties; the wine of the country is not appreciated. And so we have again arrived at the water, which after all is the best, cheapest and healthiest drink. Ἀριστον μὲν ὕδωρ, in spite of the German students who sing: *Cervisiam bibunt homines, Animalia cetera fontes*.

THE MAGUEY PLANT AND THE MAKING OF PULQUE.

The maguey plant, *metl* in the Aztec language, botanically *Agave Americana* (centennial plant in the United States, as it is supposed to bloom only once in a hundred years), called aloe in some parts of Europe, belongs to the liliacea family, tribe alströmmeria. It is indigenous in Mexico; it grows everywhere in the hot and clod lands, on dry or marshy ground. But the finer varieties, tecometl or tlacametl, those that yield pulque or tlachique, only grow in the cold and high lands, principally in the northern parts of the States of Puebla and Mexico, called the plains of Anahuac. The plant, as is well known, is characterized by an extraordinary development; the stem is solid, covered by the leaves and measures sometimes 50 cm. in diameter. The leaves are stiff, of the form of a gutter, concave on the upper side and convex on the lower. The edges of the leaves are full of thorns; the fleshy part is full of thin parallel fibers, the surface being thick like leather and shiny. When the plant is completely developed, which takes at least ten years, it is of considerable size; the leaves are over 3 m. long, more than 30 cm. wide, 10 cm. thick at the bottom, the edges lined with wreathed thorns, the upper one of them 5 or 6 cm. long. The bud is at first enclosed in a straight cone. While the whole plant needs at least ten years to fully develop, the stalk, which grows over 5 m. high, reaches maturity in a few days. The upper end of the stalk, when it blooms, spreads out in candelabra, each of them crowned at its end by a corymb of greenish yellow flowers.

A maguey plant that has flowered dies within two or three years. If the bud is cut off, which is done with a special instrument made of oak wood, and a deep hole is scraped out in the stem, the sap that was intended to form the stalk and the flower collects in that hole. That sweet sap is what they call *aguamiel*, honeywater; it contains water, sugar and gluten. A plant that is tapped in that way will die within four or six months, during which time it will continue to give aguamiel; but then the stem will already be surrounded by little plants, that only need transplanting. That is the only nursing the maguey requires.

The aguamiel is collected twice a day by means of a calabash, used like a siphon; it is emptied in raw ox hides, spread out on a wooden frame so as to form a trough, in which some old pulque dregs are thrown. There the fermentation sets in; alcohol, acetic acid,

carbonic acid and putrid fermentation are formed and in two or three days the pulque is ready for use. It is sent to Mexico in barrels or in pipes made of hog skins.

There are more than thirty varieties of maguey, only twenty-two of which are fit for making pulque. These plants are cultivated, one might say civilized; the others grow wild and are valuable only for hedges and for fiber. Since the discovery of America the maguey plant has been introduced and acclimated in the south of Europe, and all along the coast of the Mediterranean Sea it grows without culture and like an indigenous plant, giving the landscape a characteristic aspect. The maguey is one of the most useful plants; an Indian might almost live on maguey alone.

Messrs. P. and J. Blasquez, to whom we are indebted for many details about the maguey, give the following enumeration: The underground part of the stem, ground with some maize, is made into cakes. Some varieties give a brandy; the stem fried and distilled gives the brandy called mezcal and tequila. Agnamiel, pulque and tlachique are drunk extensively and often to excess. Old pulque may be converted into excellent vinegar. The stalks are used as poles to build huts; the leaves furnish the roof; the thorns are used for needles and nails, the skin of the leaves for sandals, the fiber of the leaves, pita, for thread and is also made up into ropes, textures and paper; the coarser fibers furnish brooms and a kind of brushes; the roots are used for soap. When the bud is torn off there is found a coil of fiber which weighs half a pound and is as fine as silk. The dry leaves, stems and roots are used for fuel. The bud, half fried, becomes sweet and furnishes food for the poor. The tender flowers, mixed with eggs, make a kind of omelet.

A species of butterfly, *Teria agaves*, *Papilio agaves*, lays its eggs in the fleshy leaves of the maguey; in the next spring the caterpillar is formed. It is about two and one-half inches long and of the thickness of a finger. The Mexicans dig them out and eat them fried, with salt and red pepper. These worms are considered a great delicacy; they are said to taste like almonds or hazelnuts. We have never tried them. Besides this the maguey is the habitat of another kind of butterfly, *Bombyx agaves*, and of two species of hemipterous insects, *Lystra bombycida* and *Velia agaves*.

THE PREVALENT DISEASES.

The prevalent diseases and those which cause the greatest mortality in the Mexican Republic, according to a valuable work of Dr. Orvañanos: "Geografía Médica de la República Mexicana," and of course different according to states and localities, are: Continuous fevers (including, I suppose, typhus, rheumatism, etc.); pneumonia (with bronchitis and catarrhal affections of the respiratory organs); intestinal affections (dysentery and catarrhal, in great part due to abuse of alcohol); intermittent fever (including pernicious, remittent and malarial); leprosy exists in certain parts, and pellagra and "*el pinto*" a cutaneous affection not sufficiently studied (in the States of Guerrero, Michoacan, Tabasco and Chiapas); goiter, cretinism occurs, deaf dumbness (limited); yellow fever (endemic on the Gulf Coast, in certain districts of the States of Vera Cruz, Tabasco, Campeachy and Yucatan; epidemic occasionally in large parts of the

country, always confined to the coasts, but of both oceans); cholera visited almost the entire country in the thirties; smallpox, general, doing great havoc, as vaccination is not properly attended to; measles and scarlet fever; diphtheria (the Mexicans pretend that it was unknown until the last invasion of the French, who are said to have imported it; not extensive); whooping cough (limited).

Pneumonia and bronchial troubles, common and deleterious, principally in the higher parts of the country and during the cold season (fibrinous rare) and many other diseases; rabies occurs, so does lithiasis; liver abscess, even in persons who have never lived in the hot country nor had dysentery; tuberculosis is not frequent, but especially deleterious in the hot lands; tetanus, not rare in the hot low lands, traumatic as well as neonatorum; snake bite very rare; insolation never heard of.

One of the particular features of our climate is the almost total absence of typhoid fever. Indeed, most of the Mexican physicians assert that it never occurs. I myself, and other foreign physicians who have observed typhoid in Europe, am not of that same opinion, but we admit that it is quite rare and never takes an epidemic form.

Another strange phenomenon is observed with regard to typhus. That disease is endemic and epidemic all over the elevated table land and causes numerous deaths. It seems that an elevation over the sea of less than 4,000 feet is quite unfavorable to its production and establishment and we may practically say that it does not occur in the low lands. Here Dr. Orvañanos is decidedly mistaken in his geography, when he says that typhus occurs in places where physicians of thirty or more years practice affirm to have seen but one case or none at all, and those isolated cases might have been imported.

It would seem that the habitat and conditions of development of yellow fever and typhus are precisely the reverse and that where one is endemic the other does not find a favorable ground. How that is remains unexplained until now.¹

VICIOUS READING DISTANCE AS A CAUSE OF ASTHENOPIA.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY CHARLES HERMON THOMAS, M.D.

PHILADELPHIA, PA.

The review in outline of a single typic case must serve to illustrate the present topic.

J. B. J., male, student, aged 15 years, consulted me in October, 1896; wearing weak, minus compound cylindricals giving vision $\frac{5}{6}$ in each eye. It was stated that the refraction had formerly been hyperopic and the progress of the myopia rapid; had been refracted some months previously at competent hands and no additional myopia had since developed. Glasses were left unchanged. Muscular tests, including tropometer, gave no indication of heterophoria. Ophthalmoscope shows slight striation with slightly heightened color. Asthenopic symptoms were very distressing. He complained chiefly of brow pain on use of the eyes in reading, which was accompanied by nervous depression of a disabling character. These symptoms, however,

¹ With this paper was shown a box containing Mexican plants that were used for prizes, sent by Dr. Semeleder specially for this Section.

were absent during vacation periods. He had much difficulty in his school work, was backward in his classes, at least two years behind those with whom he started, though he was intellectually bright and a member of a talented and scholarly family. The question of his entire removal from school was, and for some time had been, under consideration. The book in reading is held habitually at something less than *seven inches*, though as his vision for distance would indicate, he reads the smallest type at thirteen to fifteen inches with entire ease. I advised the strict adoption of a thirteen-inch reading distance, which being tested for one week, complete relief of symptoms was reported; he has been able to keep up with his studies without difficulty. Two months later the same favorable report was confirmed.

I refrain from the further citation of cases, though my note-books show a number closely allied to the one just related. Many must have seen cases of this class, notwithstanding which it is probable that they are not as frequently recognized as their importance calls for. Plainly in this instance the asthenopia and the nervous symptoms were of combined accommodative and muscular origin due to the vicious reading distance. It will be seen that the strain here thrown upon the ciliary muscle amounted to about 3 D. beyond that normally employed, aggregating when the eyes were used in reading about 6 D. of accommodative effort; while at the same time there was an equivalent muscular strain involving a like number of meter angles of active convergence.

The habit of holding the eyes too close to the work is one common among school children, and experience shows that many of them can not bear the strain involved without serious ocular and nervous damage.

Vicious reading distance, as a cause of asthenopia and apart from its relation to myopia, appears to be deserving of more consideration than it has yet received. As to the cause of the condition, it is doubtless a continuation of the habit of infancy of holding objects close to the eyes to obtain the larger retinal images; aggravated and confirmed by faulty relations of study tables and school desks. As to its correction the prognosis is not always encouraging. Few patients will be found to yield such implicit obedience as did the one in question. Indeed the difficulty in securing any considerable improvement in this respect, even with the aid of teachers and parents, is often almost insurmountable.

1633 Locust Street.

DISCUSSION.

Dr. EDWARD JACKSON, Philadelphia. This matter has seemed to me to be one of a great deal of practical importance, but one of its direct difficulties is to get patients to realize this. I think some times after an elaborate examination and the prescribing of glasses, that if we bring out the point that simply by holding the book one, two or three inches too close to the eyes the patient can undo all the good work of the glasses, he might be induced to appreciate the importance of it.

The harm of excessive accommodation is perhaps not fully measured by the number of diopters, if our theory of accommodation is correct, and it depends on elasticity of the lens. The lens acts like a spring, and we know it takes more force to affect a spring after it has been deflected than to deflect it to the same extent in the start. The same principle may apply to the work of the ciliary muscle. A patient using 3 D. of accommodation more than necessary is giving more than twice the effort necessary for 3 D. of accommodation.

There is a reason for this vicious working point in the fact that the larger images are easier of mental recognition than the smaller ones. That accounts for the habit that all infants have of holding things very close.

Dr. J. A. LIPPINCOTT of Pittsburg—I have had an opportunity of observing several cases of the kind reported without esophoria in the majority, but in one with esophoria it seemed to be sufficient to account for the malposition. I found all the cases benefited or cured by wearing a frame attached to the head, upon the distal end of which was a support for holding the book to be read. In that way the patient can not move the head without moving the book, and the proper distance is maintained.

Dr. WILLIAM THOMPSON of Philadelphia—I have under my care now a case very nearly like the one reported. A very intelligent lady is preparing herself for the position of librarian and she is anxious to do many hours of near work. A few years ago she had 3 or 4 D. of myopia; it is now about 6 D., but she is wearing her old glasses which I allow her to use. She has about 2 degrees of esophoria. I have found it impossible to make her read at the proper distance though she has been told over and over again. When she writes she puts her head down with the nose almost against the paper. She suffers with headaches because she persists in removing her glasses and reading within her far point.

THE USE OF FULL CORRECTION CYLINDRIC GLASSES IN ALL CASES OF ASTIGMATISM.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS J. LAUTENBACH, M.D.

PHILADELPHIA, PA.

I believe that the entire correction of the astigmatism present in every eye, is a necessity, that is, provided the eye is used at all for near work. If there is no use for a knife there is no need to sharpen it, but just as soon as the eye is used as an instrument for seeing, its refraction must be so adjusted that the ciliary muscle fibers act equally, and not unequally as in astigmatism, to produce a clear, distinct image on the retina.

The disturbances of the recti muscles of which we hear so much today are in a great part but a development of nature's effort to allow the tired ciliary muscle some rest by presenting on the retina an image which requires other fibers of the muscle than those previously exhausted, to do an extra share of work, relieving those which have become tired from overuse. Of course the neurotic element in developing recti disturbance is a very important one, but is often only the reflex condition brought about by the train of pathologic circumstances portrayed.

In addition to the effect on the recti muscles exerted in the manner described, there is still another influence at work whenever there is present any astigmatism whatever. In a paper presented to this Section at the Baltimore Meeting, I advanced a theory as to the formation, retention and want of retention of the normal corneal curvatures, and I think demonstrated that the recti, oblique and the ciliary muscles were, in addition to the influence of the eyelid, the pressure of the orbital cavity and structures, concerned in the retention and alteration of the corneal meridians. In a paper recently printed in the *Ophthalmic Record*, I recorded some observations on the influence of nasal affections on these curves, exerted through reflex influence on the recti and oblique muscles. Now, if the muscles can and do affect the curvatures, does it not seem reasonable that the reflex influence of an indistinct image on the retina and an unequally tired ciliary muscle can and does exert itself on the oblique and recti muscles to such an extent as to occasion insufficiency of the recti with disturbances of the obliques as well, and does it not then

follow that some of the cases which now have prisms used, and others in which graduated tenotomy plays an important part, are but such in which the muscular balance should not be interfered with, as the inequality of the muscular action is but Nature's method to relieve a pathologic condition by the rest cure? Should we not rather re-examine the eye as to the refractive error, especially as to the amount and axis of the astigmatism present, correcting it fully, as it may have varied since the preceding examination, not being always a constant quantity. Then, in addition, give the eye the nearest approach to perfect rest possible by abstention from close work.

I feel confident that if in cases of disturbed muscle balance, work in accordance with the suggestions here presented be instituted, there will be quite a group of these cases which will be curable without any thought of operation or of propping up of the apparently weakened muscles by prisms.

The theoretic conditions seem borne out by practical experience, and, in fact, they have been suggested by the results obtained through the re-examination of heterophoric eyes and the use of full astigmatic correction glasses.

DISCUSSION ON PAPERS OF DRS. DEAN AND LAUTENBACH.

Dr. L. J. LAUTENBACH of Philadelphia—There is a thought that I would like to give voice to here, and it is a growing one, that is that the lenticular astigmatism does not remain constant, but varies, under some conditions, from moment to moment. I have had a patient wearing astigmatic glasses correcting in part the corneal and lenticular astigmatism, using one set of glasses for near and another for far work and I have tried in every possible way to obtain a glass that would combine the same cylindric effects, and have failed to do so.

Dr. J. A. LIPPINCOTT of Pittsburgh—In regard to the statement made in the paper, there was no way of explaining the discrepancy between the general refraction and the corneal refraction as given by the Javal ophthalmometer except by the lenticular astigmatism. I have not very infrequently seen, in cases from which cataract had been removed, a decided difference between the real refraction and the corneal refraction as shown by the ophthalmometer. This astigmatism I assume to be found in a peculiar curvature of the posterior part of the eyeball. The posterior curvature of the cornea may perhaps be an influential factor, the anterior portion being the part determined by the ophthalmometer.

Dr. W. L. THOMPSON of Indianapolis—Did I understand Dr. Lautenbach that he would correct the full astigmatism no matter how high the degree? Would you if there were five or six degrees in the vertical meridian and as much in the oblique? I would expect the patient to have diplopia under the circumstances.

Dr. G. E. DEAN of Scranton, Pa.—Dr. Lautenbach brought out one interesting point in regard to the rapid variation of the conformation of the lens. This may be the reason why so many cases, after very careful correction by good oculists, change within the first eighteen months and require a re-examination and stronger correction, and then remain in the same condition for several years. I have seen a patient while being examined by the ophthalmometer change the conformation of the lens to the extent of 0.5 D. and it is a very interesting thing to watch. It is done by muscular action. In regard to Dr. Lippincott's point, I did not intend to exclude the conditions at the posterior pole of the eye.

Dr. L. J. LAUTENBACH of Philadelphia—In answer to Dr. Thompson, I would say that I never fail to order a full correcting cylinder, but may vary the general refracting glass.

Medical Law Unconstitutional.—According to the *Idaho Daily Statesman*, the medical law in Idaho has been declared unconstitutional, having passed the Senate irregularly. This was the decision of the Supreme Court, December 4, in a case brought to compel the Board of Medical Examiners to issue a license to the plaintiff to practice medicine. The decision virtually makes the Board of Medical Examiners a thing of the past.

EXAMINATION OF THE EYE BY OBLIQUE ILLUMINATION, WITH THE BINOCULAR MAGNIFIER.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD JACKSON, A.M., M.D.

PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC;
SURGEON TO WILLS' EYE HOSPITAL.
PHILADELPHIA, PA.

The original form of the binocular magnifier was that of two partial lenses cemented together at an angle. Its proportions were not what have since proved to be the best, but they were sufficiently good to make it a very practical working instrument, as soon as it had been learned how to use it. But the writer's first attempt to employ it, persisted in until it caused severe eyeache and headache, resulted in complete failure; so that the lens was thrown aside for weeks before the second attempt was made. The same difficulty has been experienced by others.

The use of such lenses seems easiest to young persons who have worked little with optical instruments, and are accustomed only to normal binocular vision. In proportion as one has learned to use monocular optical instruments, like the microscope and ophthalmoscope, and especially the ordinary magnifier or corneal loupe, is the difficulty of learning to see through the binocular magnifier increased. Still this difficulty is not, for any one, greater than the difficulty of learning to use the ophthalmoscope; and when once you have learned to see through it the difficulty of the instrument has been overcome. The appearances that are to be studied with it are those with which we are already familiar by binocular vision, or through the monocular magnifier, only that these appearances are with this instrument more striking and definite, and the finer details are brought out and made more prominent. The first difficulty is greater than most persons would suppose; but that first difficulty having been mastered it is an easy instrument to use.

Figure 1.

The difficulty is decidedly greater with the simple decentered double lens (Fig. 1) than with the lenses and prisms mounted in separate tubes. One reason for this is, that with the former one eye can see both halves of the lens, and the surgeon accustomed to exclude one eye in working with other optical instruments, invariably does the same with this and becomes conscious of the double images seen by one eye through the two halves of the lens, instead of selecting and fusing the proper images presented to the two eyes, and excluding what is, in this examination, irrelevant.

Another difficulty experienced with this original form of the lens comes from the reflections from its

surface. In a room with diffused illumination this may quite prevent one from seeing through the lens, even though he be familiar with its use. In a room properly darkened for oblique illumination such reflections are readily avoided.

The later form of magnifier, inclosing the lenses in the tubes (Fig. 2), gets rid of annoying reflections altogether. It also prevents one eye from seeing through both lenses. With this form of instrument, I have not found any one possessing good binocular vision, who could not get the binocular effect at the first attempt with the magnifier, although it might readily happen that false adjustment of the instrument, or the holding it improperly with relation to the eye looked at, or with relation to the surgeon's eyes, would prevent this.

Figure 2.

Every ophthalmic surgeon knows that any new pair of glasses must be used for some little time before they will prove satisfactory. This is eminently true of such strong lenses as are furnished in the binocular magnifier, especially as they are used quite intermittently. One has, with it, to learn the fusion of images rather more diverse than he has before attempted to fuse; and perhaps it should really be a cause for surprise that so many ophthalmic surgeons have so quickly gained sufficient familiarity with the instrument to make it of practical service.

Adjustment.—The most important point in the adjustment of the instrument is that the prisms shall be so turned as to bring the two images for the respective eyes to the same level. Any one free from hyperphoria can make this adjustment by holding the lenses at rather less than their focal distance from a sheet of paper on which is a straight line. The instrument is held with the bar joining the two tubes parallel to the line which is to be seen through the tubes, the right eye looking through the right tube, the left eye through the left. The eyes are not brought close to the diverging ends of the tubes, as in using the instrument, but are withdrawn some inches from them, so that the portion seen through one tube does not appear to coincide with the part seen through the other tube, but the two areas appear to lie side by side, each crossed by the line which is used at a test. Under these circumstances the line should appear continuous across both areas. If in one area the line appears higher, it shows that the

apex of the prism of that side is directed too much upward, and this is to be corrected by properly rotating the prism, having first loosened the screw that binds it. When the line is thus made continuous across both fields the instrument has been adjusted, and the binding screw should be again tightened. The best adjustment is with the bases of both prisms turned exactly toward the nose, in which position the line appears continuous in the two tubes, and when made to cross the middle of the field is also continuous with the line as seen outside of the tubes. But if both prisms are turned equally up or equally down, a slight deviation from this exactly horizontal position of their bases is of no practical importance.

In the matter of adjustment of the width between the surgeon's pupils, no special attention is necessary, since it matters little whether the surgeon's pupil comes opposite the nasal or the temporal portion of the prism. The adjustment can, however, be effected by varying the distance of the lenses from the surgeon's eye. The diverging ends of the tubes are close enough together to suit a very narrow interpupillary distance, if the eyes are brought close to the end of the tubes; but by withdrawing the eyes from the ends of the tubes the widest interpupillary distance can be equally well accommodated.

In adjusting the position of the object it must be borne in mind that with this instrument each eye can see only within a tubular space, and both eyes can see the same object only when it is held at the intersection of these tubular spaces. The lenses and the inclination of the tubes are calculated to give emmetropic eyes distinct vision, with little or no effort of accommodation, at the distance of this intersection. If one has high myopia, he must either have the lenses in the instrument replaced by weaker lenses; or he must have the instrument adjusted so that the tubes will meet at a slightly greater angle, so that the intersection of their fields of vision will occur closer to the lenses. To be used by a surgeon of high hyperopia, the tubes of the instrument should be more nearly parallel, or the lenses should be made correspondingly stronger.

Aberration.—The surfaces of the lenses are so selected as to reduce spherical aberration to the minimum, by making the radius of curvature of the surface toward the surgeon's eye the shorter, and the reducing of curvature of the surface toward the object. The simple lens is made plano-convex, and the proportion is 1 to 6 for the lenses mounted in tubes. Some aberration may, however, be noticed at the periphery of the field, with the stronger lenses employed. The field has been made as large as was available, without resorting to some combination for the correction of aberration. It has seemed to the writer that simplicity and cheapness were very much more important than the slight gain to be made by correcting aberration through the use of a complex lens.

Chromatic aberration is never noticed except when one looks at black lines on a white ground. Then it becomes perceptible, although the two eyes correct each other so that in the center of the field the lens gives no chromatic effect. What dispersion does occur at the center of the field is due to the prism. Now the prism before the right eye (with its base to the left) gives to a black line running perpendicular to the visual plane, a red fringe on the right border and a blue fringe on the left. The left eye, looking

through a prism with its base turned toward the right, sees the same black line with the red fringe on its left side and the blue fringe on its right. If the lines be brought to the center of the fields for both eyes, so that dispersion is as great in the one image as in the other, their combination in binocular vision causes the color effect to almost entirely disappear, giving an achromatic image.

If, however, such a line be seen at one side of the field, the colors seen by the eye of the same side will predominate and become noticeable in binocular vision. If while looking through both tubes, one eye becomes excluded from the visual act, as by habit from the use of other optical instruments, the colors seen by the eye used may be noticed. For looking at objects like the anterior segment of the eye, that do not present the especial contrast of black and white, no chromatic aberration is noticed.

Strength of lens.—The stronger the lenses employed the closer must they be brought to the eye looked at when in use. The strength that it is possible to employ is therefore limited as the strength of the monocular corneal loupe is limited. The strength of lens, of course, directly determines the magnifying power. The writer had supposed that within such limits the greater the magnifying power the more useful would the instrument be, but experience shows that this is not the case.

For studying certain minute details of the iris or cornea the strongest lenses that can be used, probably about one-half inch lenses magnifying 20 diameters, may be of service. But for ordinary clinical work, including the inspection of the cornea and iris, much weaker lenses will be found of more general service. Thus, even the one-inch lens is too strong to see at the same time, with comfort and profit, the iris in normal position and the cornea. A weaker lens, as the 2 inch, 20 D., will give a much better idea of the depth of the anterior chamber; and is quite as good in discriminating the depth of opacities in the cornea and crystalline. In general, it may be laid down that it is wise for the surgeon to start with the binocular lens, not stronger than the monocular magnifier that he has been accustomed to employ.

Value.—The benefit of the binocular magnifier in giving a better idea of the relative depth of the objects seen is obvious. An equally important benefit, which would scarcely be expected from *a priori* consideration, lies in the increased vividness of the impressions from binocular, over those obtained in monocular vision. We are accustomed to think that one eye can see just as much as two. And in a strong light, for the recognition of perfectly familiar objects, this may be almost true. Still, even with the best illumination, and such familiar objects as test-letters, if the two eyes see about equally well there is always a distinct gain in acuteness of vision when the two are used together.

If the illumination becomes feeble this gain is very much greater. If one trying to find his way in a darkened room will cover one eye, he will notice a very great reduction in his power of recognizing objects. Something of the same sort is true of vision with the best illumination, if the objects to be recognized are unfamiliar. Only one who has tried it can appreciate the increased force and definiteness of the visual impressions, obtained through the binocular magnifier. By such impressions points will very often be recognized that would otherwise quite escape the

observer; although after his attention was drawn to them he might be able to make them out fairly well with the monocular image.

Of the use of the instrument mounted on a head-band, Fig. 3, for operations I have only to say that it is a great help in the removal of small foreign bodies from the cornea, and in operations upon the iris or lens capsule. In certain points, as the recognition of incarceration of the iris, or in the opening of the lens capsule, it is a decided help for cataract extraction. Of course, weaker lenses which would be of service in other operations, could be mounted in this same way. Yet as they were made weaker the advantages of the instrument over a special pair of operating spectacles would diminish. Probably with lenses of the same strength as those so far employed in eye work, or even with stronger lenses, the instrument may be found serviceable in dentistry, and in certain operations on the skin and hair bulbs. It seems certain that the binocular simple microscope will give very important aid as an instrument for study and investigation in the biologic sciences.

Figure 3.

The different forms of the magnifier are made by Messrs. Wall & Ochs of Philadelphia.

DISCUSSION.

Dr. C. F. CLARK of Columbus—I would like to ask whether, in case of hyperphoria that does not require correction for comfort, Dr. Jackson would consider it worth while to have an instrument constructed with particular reference to that, or should it be corrected on the glasses being worn.

Dr. JACKSON—I think an amount of heterophoria that might not cause serious trouble in the ordinary use of the eye might be a considerable obstacle to learning the use of the instrument, particularly if it were hyperphoria. It can be readily compensated for, however, by simply turning the prism, which is adjustable.

CONGENITAL OPACITY OF THE CORNEA.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY H. MOULTON, M.D.

FORT SMITH, ARK.

The recent articles by Tepljaschin (*Arch. Ophth.*, Vol. xxvi, p. 74) and by Barbacheff (review in *Ophth. Rec.*, Vol. vi, p. 88) have stimulated interest in the rare anomalies of corneal transparency of congenital origin.

The point of practical interest is to determine whether such a case is due to arrested development or

to an inflammatory process, especially interstitial keratitis of syphilitic origin *in utero*.

My case was that of a boy seen Nov. 14, 1896, at that time 8 years old. The case had also been seen by my colleague Dr. W. G. Smith in January, 1890, who noted as follows: "Total opacity of left cornea, said by parents to have been present from birth. The parents also stated that opacity would sometimes clear up so that the outline of the pupil could be seen. V.=Pl." There was no record made of nystagmus, but a concomitant convergent squint was noted. To me the parents made the same statement, viz., that the opacity was discovered within a few hours after birth, and that there had never been any redness or secretion about the eye. This statement can be credited, for the father was of sufficient intelligence to have observed correctly. The opacity occupied the whole of the cornea but was most dense in an area above and to the nasal side of the center. It was least dense below and to the temporal side, and through this latter area by focal illumination the outline of the pupil could be dimly observed. The superficial and middle layers were the ones that were opaque.

The diameter of the cornea was found by measurement to be 1.5 mm. less than that of its fellow.

The right eye also presented interesting conditions. The cornea was perfectly transparent and the eyeball was normal in shape and size, but the eye was myopic and amblyopic. $V.=\frac{1.5}{20}$. Under a strong mydriatic with -5 D. Spher. $V.=\frac{1.5}{89}$. Owing to nystagmus the fundus was difficult to explore, but changes were made out in the papillo-macular region. These consisted of a thinning of the retina and choroid, greatest at the temporal side of the disc and of a pigmented stippling about the macula with a few pin-head sized spots of pigment irregularly placed about half way between the macula and papilla. A marked horizontal and rotary nystagmus affected both eyes. After wearing glasses a few weeks this still remained, but to a much less degree.

The parents gave no history of syphilis and neither they or the boy presented any objective evidence of it.

It is needless to call attention to the fact that the best text-books have very little to say on this subject, and that cases are very seldom met with or reported. I shall not take up time with an account of the literature, but I have imperfectly studied the published accounts of ten cases. No two of them were alike, and in none of them was the opacity complete. Manz remarks that cases of congenital total opacity are extremely rare. In six of these cases both eyes were affected; in four, but one eye. Of the first, three were stated to be developmental and three inflammatory. Of the latter, three were developmental and one inflammatory. In each instance the inflammatory cases were traced to interstitial keratitis of syphilitic origin. From these cases it would seem that where a single eye is affected, arrested development is most likely to be the cause of the anomaly. Another fact is made indisputably evident, viz., in all the cases of syphilitic inflammatory origin the deep layers were the only ones affected by the opacity. This was proven microscopically in some of the cases. In all the cases where the changes were described as developmental, these changes were found in the superficial layers. This observation is of value in deciding upon the etiology of a given case, and with other data in my own case, places it in the category of developmental anomalies.

Besides these two main forms of congenital opac-

ities De Wecker describes two other subtypes of the inflammatory variety, viz., those occurring in buphthalmos, and those in consequence of embryonic perforations of the cornea. But the two main types are the ones in which chief prognostic, diagnostic and therapeutic interest centers.

ANOMALIES OF THE RETINAL PIGMENT EPITHELIUM AND THEIR CLINICAL SIGNIFICANCE.

Presented in the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY H. GRADLE, M.D.

CHICAGO.

The homogeneous appearance of the normal fundus of the eye depends in part upon the integrity of the retinal pigment epithelium, which acts as a turbid medium obscuring the structures behind it. Whenever these cells contain no pigment, or less than the usual amount, the choroidal vessels become visible, as in albinos and often in myopic eyes. In the present paper, however, I propose to consider not the absence of pigment, but the appearance due to its irregular distribution.

Structural changes in the retinal epithelium have been demonstrated anatomically by Donders, H. Mueller, Leber, Goldzieher and Fuchs, and were attributed by them to the influence of globular hypertrophies ("Drusenbildung") of the vitreous lamella of the choroid. According to Rosa Kerschbaumer (v. Graefe's *Arch. f. Ophth.*, Vol. 38, I., p. 217) anomalies are found in the pigment epithelium in three-fourths of all eyes of persons over 50 years of age, but are confined mostly to the anterior (ciliary region) and extend only exceptionally toward the posterior pole. According to Kerschbaumer's description some cells increase in size even up to six times their normal dimension, and lose their well-defined contours. Their nuclei multiply and karyokinetic figures appear; degeneration takes place, the nuclei refuse stains, become pale and vacuolated. In some instances the entire cell disintegrates, leaving its pigment in a mass on the basal membrane. Some cells contain an increased amount of pigment, others less than normally, or none at all. The pigment grains themselves may lose their rod-like shape and become round, small and dark brown. Larger round masses of pigment may also be seen between cells. On the other hand, rarefaction of pigment alone may occur without other visible changes in the cells. Sometimes small areas are thus found devoid of coloring matter.

Since these changes incident to advanced age are mostly confined to the anterior part of the fundus, invisible to the ophthalmoscope, or seen only imperfectly, they seem to have been but little studied during life. There are, however, certain easily observed ophthalmoscopic appearances which can only be referred to similar anomalies of the pigment in the retinal epithelium, although these changes have not yet been anatomically demonstrated. I refer to the stippling or granular appearance of the fundus seen con-

monly around foci of choroiditis or retinochoroiditis. I have also noted the same granular condition during the retrogressive stage of optic neuritis, in which cases it seemed most pronounced in the area adjoining the optic papilla. In purely retinal lesions I have never observed this peculiarity.

The special object of this paper, however, is to call attention to the frequent occurrence of the same appearances in the fundus of children and young people suffering from severe asthenopia. While the healthy fundus of adults presents almost always a homogeneous appearance, I have observed a more or less pronounced stippling or "granular" condition in about 5 to 8 per cent. of young people examined by me on account of asthenopic complaints. Since all transitions occur between a perfectly homogeneous fundus and the extreme granular appearance, such as I shall describe presently, it is obviously impossible to state accurately the frequency with which this anomaly occurs. By limiting myself to those records which are fairly complete in details, and which refer only to well-pronounced appearances in the fundus, I can base this report on the histories of forty cases. These were all instances of what I have described elsewhere as exaggerated asthenopia, ocular discomfort out of proportion to any existing error of refraction or other local anomaly present.

The ophthalmoscopic peculiarities to be described are usually most pronounced in the inferior nasal quadrant of the fundus. Less commonly they extend around the periphery of the entire ophthalmoscopic field and least often are they seen at the posterior pole. It must not be overlooked that in dark subjects the macular region has often normally a slightly stippled appearance, which however, may be considerably exaggerated in these patients.

The peculiar granular appearance of the fundus I can not describe better than by comparing it to a surface covered with a mixture of black and reddish powders with preponderance of the latter. Most of the separate grains are barely within the range of visibility; occasionally a few larger black points are seen sometimes, but less commonly a few white specks of pin-point size can be found. There are often in the same fundus small areas with so little pigment that the choroidal vessels become visible. When the rarefaction of pigment is not so extensive the surface appears, in the words of Loring ("Text-book of Ophthalmoscopy," I, p. 50), not "smooth and hard like a cloth with no nap to it," but "like one that has a plush or velvety feel." Some authors presumably mean this condition when they speak of a "wooly fundus." The condition is always symmetric in both eyes, though sometimes more pronounced in one.

There are probably various reasons why these appearances have been so little noticed in literature. Occurring in eyes not otherwise diseased, they are easily overlooked, especially in the inverted image, unless specifically searched for. Moreover, when not pronounced these appearances would be classed by most observers as within the normal range unless systematic comparisons were made. Yet the infrequency of this granular appearance in perfect eyes and its striking occurrence in connection with fresh choroidal disease suggest positively that it is a deviation from the normal type.

The subjects in whom I have observed this peculiar fundus were all of the neurotic type. In fact the

most striking appearances were found in the most pronounced cases of nervous disturbance. The most extreme instance I have ever seen was in the case of a boy with very low vision, presumably due to some obscure brain lesion, but without ocular disease, where the fundus could literally be called finely "speckled." As evidence of the neurotic state I have on my records the histories of frequent headaches, chorea or habit-spasm, general restlessness, emotional irritability and sometimes other manifestations of general neurasthenia, such as fatigue on slight exertion, and insomnia. Very often the nervous condition was due to heredity. In other instances it could be referred to improper nutrition during infancy. In some, presumably digestive disturbances were of influence and a few times anemia co-existed, perhaps had preceded it. The ages ranged from 5 to 22 years with preponderance of the period from 8 to 15 years.

All these patients complained of ocular discomfort described sometimes as a burning, rather oftener, however, as an ache, and usually accompanied by more or less headache. While reading intensified the discomfort, most patients complained more or less even while resting the eyes, and indeed, very commonly, much discomfort was noticed at once on rising in the morning. Perhaps this was due to the effect of daylight upon the eye sensitized by darkness, for as a rule these patients were annoyed by strong light of any kind.

No indication was found that the pigment changes affect the acuity of sight. While perhaps a large number of the patients had less than perfect vision, there seemed to be no relation between the lowered vision and the amount of stippling either in the periphery or in the macular region. In no case was there any history of gradual failure of sight. Amongst forty patients (after the correction of all ametropia), V. was 20/20 or over in 10, 20/20 to 20/25 in 12, 20/25 to 20/30 in 12, under 20/30 or over in 3, and under 20/30 in one eye only in 3. In no case was there any intra-ocular lesion found to account for the low vision. In most instances the presumable cause must have been irregular astigmatism. Of the three patients with vision under 20/30, one had M. of 3.5 D.; in the other two no cause could be found for vision of 20/60. In the three instances of one-sided poor sight, the condition seemed analogous to the not infrequent amblyopia found in an eye slightly more ametropic than its fellow.

The refraction in the forty patients was: E. in 9, H. or As. under 1 Dioptre in 24, H. or As. over 1 Dioptre in 3, M. under 3.5 Dioptres in 4.

Very few so-called muscular anomalies were found. Not one of these patients had hyperphoria and none of them had esophoria over 1 degree or exophoria over 3 degrees. In thirty of them the converging power was normal; in ten, more or less reduced.

The asthenopia was of course not of refractive origin in the emmetropic patients, while complete failure to relieve by glasses proved that in fourteen of the cases with low degree of H. or As., the complaints were likewise not dependent on the ametropia present. In nine others correction of the error proved of some benefit, by allowing them to use their eyes with less discomfort, but could not be said to have given complete relief. In only four (three of these had errors above 1 D.) were all complaints stopped by glasses, as long as they were worn. Yet even these cases do

not come under the head of ordinary asthenopia due to refractive errors, since their complaints, though really dependent on the ametropia, were so decidedly more intense than we find to be the case in ametropes in good health. I have therefore come to the conclusion that in most of these patients the ametropia was only a complicating factor, and generally one of minor importance.

The pigmentary changes are not necessarily of a permanent nature. I judge so partly by the fact that I have scarcely ever seen a pronounced granular appearance in the healthy fundus of people much over 20 years of age, even when suffering from neurasthenic asthenopia of long duration. Furthermore, I have watched the fundus a number of times during months and once for several years in a patient with patches of localized choroiditis or chorioretinitis and have observed that the stippling surrounding the foci can change or even wholly disappear after the disease has come to a standstill. Six of the juvenile asthenopes in this series of forty I have been able to see for many months, and two of these I re-examined after the lapse of one and a half and six years. In all of these the pigmentary stippling seemed to have diminished to a variable extent. In the one seen after six years it had disappeared entirely, but I must add that in this one it had never been very striking.

The treatment of these patients consisted principally in relative rest of the eyes and general hygienic measures. While abstinence from eyework proved of benefit in most instances, it alone was not fully curative. Indeed, some of the children were brought to me on account of the persistence of their discomfort during school vacation. In some instances the temporary relief from the use of smoked glasses was very striking, more so than I have ever seen in any other form of functional disturbance of the eyes. In all cases in which the correction of existing ametropia gave any relief, even if only partial, the glasses were continued while under observation. For ultimate success, however, I trusted mainly to measures directed against the neurotic condition, liberal outdoor exercise, sojourn in the country, bathing, correction of habits and diet, iron if required and sometimes strychnia. About one-third of the patients lost their eye complaints and headache under this treatment, in the course of months; another third were improved to a variable extent, while the balance could not be watched a sufficiently long time to be recorded regarding the final outcome.

The exact significance of the pigmentary changes described is not made plain by these observations. It must not be forgotten that cases of very similar clinical history, *but with homogeneous fundus*, are not uncommon. On the other hand, the frequent association of stippling and granular appearance with this exaggerated asthenopia of young subjects and its rare occurrence in eyes without complaint suggest a definite relationship. It does not seem probable to me that the changes in the pigment epithelium are the direct cause of the asthenopia. Yet they presumably contribute to make the eye more sensitive. The occurrence of similar changes in these cells around choroiditic foci suggests that they may result from nutritive or circulatory disturbances in the choroid. What role such disturbances play in asthenopia of the type described we do not know. At any rate the greater prominence which the pigmentary changes present in markedly neurotic subjects raises the ques-

tion whether instability of the central nervous system may not reveal itself by the liability of the retinal pigment epithelium to structural changes. For these cells like the retina proper are embryologically a part of the brain.

DISCUSSION.

Dr. G. E. DE SCHWEINITZ of Philadelphia—I have also observed the cases he has described as if grains of powder were dusted over the fundus. We used to call these cases, when I was in the Hospital, powder-grain fundus; I think Dr. Risley gave it the name. I have not noticed any relation between asthenopia and this fundus condition. In the most pronounced case I ever saw I thought of having a consultation with some of the older men because I thought there might be some unusual change going on of grave importance, which I had never seen. It would be interesting to get one of these cases for histologic examination.

Dr. HAROLD GIFFORD of Omaha—I would like to ask if Dr. Gradle has not examined a large number of children that complained of nothing whatever and yet presented the same kind of changes in the eye. I think it is purely an anatomic condition and has nothing to do with the asthenopia.

Dr. EDWARD JACKSON of Philadelphia—I think I have noticed something of the kind among school children, at least such cases occur without being noticeably connected with eye symptoms. Two of the most striking cases I recall now occurred in young persons under 20, and the father of one of them presented very much the same appearance.

Dr. CASSIUS WESTCOTT of Chicago—I have observed a number of these cases and have studied the condition chiefly in the children. I did not relieve by correction of the error of refraction and that has made me think the condition accountable for the asthenopic symptoms. I have not as Dr. Gifford suggests examined any number of children without errors of refraction to see whether the condition exists.

Dr. A. B. HALE of Chicago—My dispensary work is done near a large manual training school and I examine a great many children that have nothing at all the matter with them; I have not seen these conditions.

Dr. J. A. LIPPINCOTT of Pittsburg—My attention has been drawn in this direction also and I used to think the changes were pathologic, but I have seen so many cases in which there was nothing of the kind and in which the asthenopic symptoms were quite as pronounced that I began to doubt my conclusions, and then in examining a great many otherwise normal eyes I have found this condition. At the same time I think it is a very important point and we are indebted to Dr. Gradle for calling attention to the subject so that we may investigate it in the future.

Dr. J. B. JENNINGS of St. Louis—Some years ago Dr. Gunn of London, described very minute yellow dots in the retina, which he thought were always present in the cases of asthenopia, but I have never been able to see them even when he tried to point them out; still it may be well to make a search for them.

Dr. FRANK ALLPORT of Chicago—I have had an opportunity within the past four months of observing quite a number of typic Gunn's dots, especially in the region of the macula, among children.

Dr. HERBERT HARLAN of Baltimore—I have seen several cases where there were asthenopic symptoms that were relieved by glasses and some where there were no symptoms whatever.

Dr. GRADLE—I expressed some hesitation at the end of my paper in interpreting the phenomena. I did not say they caused the asthenopia but they probably increased the sensitiveness. I have seen it probably in cases where it did not provoke asthenopia. I always examine patients ophthalmoscopically and amongst many hundred young people examined the appearances did not seem to be present in a striking manner except where asthenopia was present, and that was always so excessive that it indicated a lessened resisting power of the central nervous system, hence I spoke of it as instability of the central nervous system.

EMBOLISM OF THE CENTRAL ARTERY OF THE RETINA.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY C. F. CLARK, M.D.

COLUMBUS, OHIO.

The first instance in which a correct diagnosis of embolism of the central artery of the retina was made by the use of the ophthalmoscope was the classic case seen by that pioneer in ophthalmology, Von Graefe, in 1858, and described by Schweigger a few years later.

While there is a general agreement among ophthalmologists as to the phenomena of complete embolic obstruction of the central artery, the relatively rare instances in which a portion of the retina has retained its vascular supply and continued to perform its functions have been the subject of some differences of opinion among careful observers, and this fact would seem to warrant us in bringing to the attention of the profession such cases as may come within the range of our experience.

Case 1.—On Jan. 12, 1896, I was consulted by Mrs. C. E., aged 51 years, who was referred to me by her physician, Dr. Barcroft of Coshocton, Ohio, on account of the condition of her left eye. She had known of no defect in her vision until nine days before the above date, when suddenly while sweeping, she noticed what she described as a "glimmering" before the left eye and in a few moments the whole visual field clouded over with the exception of a small space near the center. Although not robust, her general health had been good with the exception of one severe attack of malarial fever from which she suffered some twenty years before and occasional mild attacks of the same disease in the spring and fall. She knew of no cause to which she could attribute the disease of the eye.

Her vision was R. E. $\frac{67}{60}$ —, L. E. $\frac{630}{60}$ —, seen only within a limited area near the disc and with this eye she could by the aid of a 4 D. sph. glass read Jaeger 9 with difficulty. The pupillary reaction could not be determined, as she had a few days before used atropia. In the right eye the visual field was apparently normal, while in the left it was irregularly elliptic and extended only from the blind spot to the macula. At a distance of one foot it measured two inches in its vertical diameter and three inches horizontally.

On examination with the ophthalmoscope it was found that the field of vision corresponded with the papillo-macular area, which was normal in color in the midst of a whitish, edematous zone surrounding the disc. The macula which, while not like that of type, complete embolism of the central artery, presented a marked contrast to the surrounding pale retina and formed the apex of an irregularly triangular island of normal tissue, the base of which was formed in part by the disc. The upper and lower borders of the triangle were formed by vessels, the lower of which seemed to be a vein, while the character of the upper one was difficult to determine, though probably of the same nature. Both this upper vessel and a smaller one which extended some distance into the center of the normal area appeared to emerge from the disc at some distance from the central vessels and could therefore be said to have their origin possibly behind the situation of the embolus. A superficial hemorrhage of considerable size was observed near the margin of the disc about the upper vessel above mentioned and a small one on the vessel supplying the central portion of the triangle. The larger veins of the retina, especially the inferior, were somewhat distended, while the arteries were all quite narrow. No vessel of the so called "cilio retinal" variety could be made out and, indeed, there was ample nutrition supplied to the normal area by other vessels without resorting to the assumption of the existence of such a supply.

Case 2.—Mrs. J. W. M., aged 34 years, was referred to me by Dr. Buckingham of Springfield, Ohio, on Aug. 18, 1896, with the following history: While walking on the street the evening of the 15th, three days before her visit to me she had a fall, which, however, seemed to her of no significance as she caught herself with her hands and did not strike her head, but on awaking the next morning she found that the vision in her left eye was very defective and the field greatly limited. No cause other than the above fall could be discovered, as her general health had been good.

A physical examination by Dr. Rogers revealed a slight, soft, diastolic murmur along the left side of the sternum, heard with maximum intensity in the fourth intercostal space four inches from the medial line and so far to the left as the axilla. The general appearance of the eyes was normal, the pupils responded to light and there was no discomfort excepting that caused by the defective vision and limited field of the left eye.

The vision of the right eye was $\frac{5}{6}$, and she read J.1 at 5 to 14 inches. In the left the vision was $\frac{3}{12}$, and the field, which was difficult to measure, seems to take the form of an irregular, acute-angled triangle, the apex of which was at a somewhat eccentric point of imperfect fixation, the center corresponding approximately with the normal point of fixation, and the base to the temporal side. Outside of this area there was absolute blindness. The portion of retina therefore which retained imperfect vision extended in the form of an irregular triangle from a point near enough to the macula to give vision of $\frac{3}{12}$ to the disc and beyond it in a somewhat irregular zone into the nasal quadrant. This corresponded approximately with what was seen with the ophthalmoscope, namely, that while there was slight, general edema of the retina, an irregular, horizontal zone including the disc and extending toward both the nasal and temporal sides and increasing in width both to the right and left of the disc was fairly clear. Two vessels of apparently somewhat deep origin extended from the disc near its center to the inferior temporal quadrant of the retina, the upper one of which seemed to pass just beneath the macula and formed a rather sharp outline to the grayish edema which was to be seen in the lower portion and to a less degree in the upper portion of the retina. A small, well defined, independent vessel of deep origin could also be seen on the opposite side of the disc extending into the nasal quadrant. Directing the patient to fix the eye as well as it was possible for her to do I obtained a visual field approximating the form outlined in the following diagram:

A. Area in which vision remains. X. Point of fixation.

The patient continued to enjoy the above vision of $\frac{3}{12}$ with the same visual field for more than three months, when her baby accidentally struck her in the left eye with a child's bow, which, without causing pain or other evidence of traumatism, instantly deprived her of this power and produced a long, narrow, cloudy scotoma in what had been the best portion of her narrow, triangular visual field. On April 16, 1897, when I saw her last, she could with difficulty count fingers at a distance of one or two feet when held so that the image should fall in the nasal portion of the limited field.

The patient, who is an intelligent observer of her own symptoms, drew the accompanying diagram to indicate the form of the scotoma which made its appearance after her recent injury, and it will be seen that it corresponds to what might be expected were an embolus to find lodgment or a thrombus be formed in the small macular artery mentioned above.

A. Area in which vision remains. B. Partial scotoma due to second accident. X. Point of fixation.

Case 3.—On Aug. 1, 1893, I was consulted by Mr. A. D. S., a botanist, 33 years of age, of good habits and of good general health, who gave the following history: While camping he awoke on the morning of the day before his visit to me with the sensation of a veil over the right eye and with vision defective in the lower portion of the field. He thought the visual field had increased since, but while a rough test revealed a normal outline for the left eye, in the right there was blind-

ness below a horizontal line through or a little above the center of the field. For three or four weeks he had been somewhat indisposed, complaining of pain in the chest. About sixteen months before, he had grippe followed by rheumatism, which did not, however, assume the acute inflammatory form. At one time, while suffering from grippe, he fainted and fell out of his chair. As the result of a physical examination made by Dr. Rankin it was determined that he had a slight cardiac murmur due to roughening which was the result of endocarditis, and as there was a tendency to recurrence of the rheumatic symptoms, he was given appropriate treatment.

His vision in the left eye was normal and the field was good. In the right eye the lower half of the visual field was defective, but the superior half was normal, as also was his central vision when tested at a distance. R. E. $\frac{1}{3}$ —, L. E. $\frac{1}{3}$ —. But when attempting to read he was hindered somewhat by limitation of the visual field, which made it difficult for him to quickly find the line beneath the one upon which his attention had been fixed. The general appearance of the eyes was normal and he complained of no pain.

The ophthalmoscopic appearance of the left eye was normal, but in the right was seen a most striking picture. The lower half of the retina presented the usual appearance, while the upper half was white and edematous. The lower border of this area of edema was clearly defined and it extended further to the temporal than to the nasal side. Above, it did not seem to extend to the extreme periphery. The arteries were a little smaller than normal and at the point of bifurcation above and near the disc there was a slight interruption of the line of light reflex which should be seen in the center of the artery.

The most important, and to me the most interesting feature of the case was a short, slightly crescentic red line lying above the apparently normal but well defined macula. This short crescent had its convexity upward, was approximately concentric with the macula and seemed to correspond with, and in fact, to be the upper segment of the cherry-red spot seen in cases of embolism of the main trunk of the central artery. In other words, the sharply defined lower border of the edematous area of the retina passed through the upper portion of the macula, and therefore, it was only at this point that the contrast was noticeable.

On Aug. 4, three days later, the patient detected some improvement in his vision in the defective portion of the field. The superior and superior temporal portions of the disc still seemed slightly swollen. The region of the macula was more evenly red and the concentric red spot above had disappeared. The outlines of the defective portion of the field of vision corresponded with those of the edematous portion of the retina as seen with the ophthalmoscope. (See diagram of retina and field of vision.)

On August 12 the superior portion of the retina had assumed a more pinkish tint, but was still far from normal and there was no improvement in the visual field.

On October 5, sixty-six days after the appearance of the embolism, Dr. Rankin reported that a few days before Mr. S.

had an attack of dizziness which he described as peculiar and not at all like that of ordinary vertigo, and his wife stated that he was for a few moments absolutely blind in the right eye. He told Dr. Rankin that on turning his head to one side he had a tendency to continue to turn it. Notwithstanding the above symptoms and marked anemia, and in spite of my remonstrances he continued his work.

On October 13 he stated that the lower portion of letters seemed slightly indistinct, which is in keeping with the fact that the upper portion of the macula was affected, but this indistinctness was not sufficient to prevent him from having vision of $\frac{1}{4}$ — in each eye improved by the correction of his hypermetropia and low degree of astigmatism to $\frac{1}{3}$ —, nor from reading Jaeger 1.

The ophthalmoscope revealed some pallor of the optic disc with slight indistinctness of outline at the upper border, possibly indicating very slight swelling. The superior retinal artery was somewhat diminished in size and the line of light in its center was very narrow, indicating marked diminution in its caliber. The dense white of the superior half of the retina was at that time replaced by an almost imperceptible blush of opacity slightly masking the normal pink beneath it. The field of vision had improved and objects could be seen at a point 15 to 20 below the line of central vision.

In June, 1894, I found that the central vision had remained good and there had been decided improvement in the visual field. The light sense was imperfect, but present in the defective portion of the retina.

On July 18, 1896, about three years after the embolism first made its appearance, a careful examination of this patient by Dr. Rogers still revealed normal central vision with a pale disc. It seemed that there was atrophy of the superior fibers of the retina and of the nerve fibers of the upper portion of the disc. The vessels in the superior portion of the retina were small and the retinal tissue was dull in appearance. In the upper portion of the visual field his vision was good. In a broad zone below the center it was dull, while the lower portion was practically blind.

Whether or not in this case the preservation of vision in the macular region was due to the existence of a cilio-retinal vessel is a question which might naturally arise, but I detected no such vessel, and Dr. Rogers assures me that in his recent examination he satisfied himself that none existed. Had there been such a supply I do not think the edema would have followed in so direct a line across the upper half of the macular region.

It is probable that there *never* was *complete* obstruction of the superior retinal artery, but it was sufficient to produce the sharply outlined area of edema which confined itself to the field of distribution of that vessel. In the macular area, however, the anastomosis of the smaller vessels with those of the inferior branch of the central artery was so complete as to preserve all excepting its upper quadrant from the temporary disturbance of function produced by the edema. Had the obstruction ever involved the whole caliber of the artery it is not probable that on the one hand the vision in the superior half of the retina would have been almost completely preserved, or on the other that the macula would have continued to perform its function so perfectly even at the time when the edema was most marked.

The fact that the edema, which in the days immediately after the occurrence of embolism, is usually found to correspond in a general way in its area of distribution with the area which remains blind, is merely an incident and does not stand in a causative relation with the permanent blindness is, I think, demonstrated by this case. It will be remembered that this edema did not extend to the periphery in the superior portion of the retina, while an examination at a later period revealed blindness of the extreme lower portion of the visual field and the ophthalmoscope discovered evidences of atrophy of the retinal tissue of the corresponding region. The lower portion of the upper half of the retina, on the other hand, which was the seat of the most marked edema, recovered almost perfect vision.

One would conclude from this, that whatever may be the temporary effects on vision produced by edema of the retina, the permanent effects in a case of embolism are produced by impairment of the nutrition of the nerve-fiber layer. If this occurs for only a limited period of time, as by cutting off the vascular supply, the nerve fibers do not seem to have power to recover their functional activity.

While the case I have just described is, so far as I can learn, unique in the fact that in it we had a crescentic or partial, cherry-red spot in the macular region, Cases 1 and 2 are of more real interest as belonging to a group which for a number of years has attracted the attention of ophthalmologists owing to the belief on the part of many, that by means of what are termed "cilio-retinal" vessels, the papillo-macular region obtains a blood supply which is independent of the central retinal artery.

In the crosier-like vessels, which in many individuals are seen to emerge apparently from the temporal border of the optic disc at such a depth in the nerve tissue as to suggest their origin in the choroid, and then curve upward and outward to be distributed to the papillo-macular portion of the retina, really belonging to the choroidal system and are not branches of the central retinal artery, we certainly should be able with the evidence afforded by the microscope and the ophthalmoscope in the number of cases of embolism of the central retinal artery which have been recorded, to demonstrate that fact. And if they are merely branches of the central artery, which having their origin at some depth in the nerve head, pass outward to its temporal sheath at a point behind the lamina cribrosa are then reflected toward its center as they emerge, and thus take the form which gives the impression that they come from the choroid, we should also be able to demonstrate that fact. That

the question is one of great importance is apparent when we consider the comparative frequency of the occurrence of such vessels and the distinctive form which they assume.

De Schweinitz ("Diseases of the Eye," Ed. 1896, p. 113) states that "in a series of examinations Land and Barrett found this vessel present in 16.7, Veasey in 14.2 and the author [de Schweinitz] in 10.6 per cent." (It is possible that these observers may have included as "cilio-retinal" vessels all vessels of considerable size emerging from the disc at its temporal margin and distributed to the papillo-macular region.)

Dr. W. K. Rogers and the writer have for a few months made notes on this point in all ophthalmoscopic examinations. We distinguished between a vessel appearing near the margin of the disc and turning directly into the retina and one which had its apparent origin beneath the scleral ring and, after being directed toward the center curved again toward the periphery. This latter crosier-like vessel we classed as a "cilio-retinal" vessel, and in the examination of 310 eyes Dr. Rogers found it present in 8 per cent., while the writer in 317 eyes found it in 10 per cent. (Had all the independent vessels of deep origin been included, Dr. Rogers' percentage would have been 27.3 and the writer's 22.3.) What anatomic proof have we that the so-called "cilio-retinal" vessels originate in the choroidal system? In a somewhat extended search of the literature of the subject I have been able to find but one instance, that of Birnbacher (*Archives of Ophthalmology*, Vol. xvi, p. 32), in which the claim that an anatomic examination has demonstrated the presence of such a vessel is supported by what appears to be strong evidence. A plate which accompanies the description of this case would certainly seem to make clear that in this instance, at least, such a vessel did have its origin in the choroid. This was not, however, a case of embolism.

The ingenuity of the theory by which the occurrence of such an anastomosing, or independent vascular branch from the choroidal system explains the preservation of the papillo-macular area of the retina when an embolism has obstructed the central artery, seems to have had a peculiar charm for all who have written on the subject and to have led many observers to accept it without criticism, and whether or not such an anomalous vessel can be proven in any instance to have coexisted with the preservation of normal vision in this area, it is certain that in many instances writers who are generally careful observers, have fallen into the error of adopting this explanation where the evidence is entirely insufficient.

Professor Laquer (*Arch. of Oph.*, October, 1896, Vol. xxv, p. 525) gives abstracts of sixteen cases of embolism of the central artery with integrity of the temporal region of the retina, which he states are all he could find recorded. In addition to these the editor of the *Archives* mentions three other cases which should be added, and I have found two more mentioned in medical journals which seem to have been omitted. These, with the case described by Laquer and the two which I have described above, make a total of twenty-four. In the literature at my command I have been able to obtain somewhat detailed accounts of sixteen of these twenty-four cases; and it may be pertinent to ask how far do the results of a careful study of these clinical cases warrant us in concluding

that true cilio-retinal vessels were the means of preserving the integrity of the papillo-macular area of the retina? In answer to this question it may seem interesting, and in view of the claims that have been repeatedly made in favor of this theory, it is certainly surprising to note that in not one instance has the existence of what has been classed as a cilio-retinal vessel been demonstrated ophthalmoscopically. In not one was anatomic evidence adduced to prove that such a vessel was present, and while only four writers claimed the existence of a cilio-retinal vessel, three of these in the context made it apparent that they did not distinguish between a "cilio-retinal" vessel and a macular vessel of deep origin.

In conclusion, I would say that beneath the statement of the time-honored theory that in embolism of the central artery a so-called cilio-retinal vessel serves to preserve the papillo-macular area by virtue of its origin in the choroidal system, we must write "not proven."

THE TECHNIQUE OF RETINOSCOPY.

Delivered in the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY J. ELLIS JENNINGS, M.D.

ST. LOUIS, MO.

It is only within the past ten years that the value of retinoscopy as an objective test in the estimation of errors of refraction, has been fully recognized. The fact that, after a little practice, the kind and amount of refractive error can be ascertained quickly, accurately and independently of the patient, has made it deservedly popular. This popularity is largely due to the labors of Philadelphia men, particularly of Drs. Jackson and Thorington, and I therefore feel that it is quite appropriate that any additions I may have to offer may receive your friendly criticism.

The mirror which I use is plane, 2.2 cm. in diameter, with a central aperture 3 mm. in diameter cut through the glass. My objection to a mirror with the sight-hole obtained by merely scraping away the silvering, is that vision is obscured by the dust which unavoidably collects on the glass and which it is difficult to remove. The annoying reflections from the margins of the sight-hole are obviated by using a very thin piece of glass well blackened about the aperture. The mirror is set in a piece of metal $5\frac{1}{2}$ inches long and $1\frac{1}{4}$ inches wide. Over this is fastened another piece of metal which, when closed, protects the mirror from dust, and when open is used as a handle on the principle of a lorgnette. When not in use the instrument may be folded and conveniently placed in the vest pocket. Either the right or left eye may be placed opposite the central aperture by merely reversing the piece of metal in which the mirror is set. (See Fig. 1.)

The light.—In my experience the most brilliant and satisfactory light is obtained from the Argand burner or the Welsbach. Over this is placed Thorington's asbestos chimney, to exclude all light except that which comes through the largest openings of the revolving discs. The light is placed above the head of the patient and just far enough back to leave the eyes in shadow. My objection to a point of light from 5 to 10 mm. in diameter placed close to the eye of the surgeon, as taught by Jackson, is that the operator's movements are greatly restricted, and there

is difficulty in focusing the light on the eye of the patient.

I have made careful tests by both methods and find one as accurate as the other. I therefore prefer the light placed over the patient's head, as it gives a more satisfactory reflex and at the same time enables the surgeon to study movements at a distance of from four to six meters if necessary.

Distance from the patient.—I always work at a distance of one meter from the patient and add a —1 D. sphere to the lens, which neutralizes the refractive error. The method of viewing the reflex at from four to six meters, as proposed by Randall, while accurate, is inconvenient, on account of the difficulty of focusing the light on the eye.

On the other hand, the determination of ametropia by measuring the variable distance of the surgeon from the patient, as taught by Jackson, is open to the objection that an error of one or two inches in the measurement would seriously affect the accuracy of the result.

Apparatus for placing lenses in front of the patient's eyes.—For this purpose I have had an instrument constructed, called a skiascope, which was described in the November, 1896, issue of the *American Journal of Ophthalmology*. We all know how difficult it is, especially in children, to get a trial frame which fits properly and keeps the lenses accurately in front of the eye. We also know how fatiguing it is and how time is consumed in making the necessary changes in lenses. With the skiascope all these objections are overcome; the chin rest and stand can be so adjusted that the pupil is accurately centered and the patient made comfortable. The surgeon, seated one meter distant, uses his right hand to hold the mirror, and with the left controls the wheel which rotates the lenses in front of the eye. A disc close at hand indicates the strength of the lens presenting at the sight-hole. The instrument is absolutely under the control of the operator and saves fatigue and time, much to the satisfaction of both surgeon and patient.

DISCUSSION.

Dr. EDWARD JACKSON of Philadelphia—Dr. Jennings' paper and instrument illustrates that there are a great many differ-

ent ways of doing the same thing, and that one always finds the way he is accustomed to the most satisfactory. Taking up some of the points mentioned, first in reference to the sight-hole of the mirror, the objection that when the glass is left dust collects on it and is difficult to remove, I have recently met by placing back of the sight-hole a thin piece of glass like a cover-slip and cementing it on, so that it is just as easy to wipe and keep dust off the mirror as to keep it off our glasses.

In regard to protecting the unused eye from light, it is sometimes a little help to close the eye that is not back of the opening, but more of the time it is a help to keep it open, particularly when you are trying to find where the light is and turn it in the proper direction. There are times when I find myself closing one eye, but mostly I work with both open. As to the position of the light over the patient's head, that is the place for it, or back of the patient, with the concave mirror, and it is also moderately satisfactory with the plane mirror when you work at the distance of one meter or over. The whole question of light depends upon having the light area as definite as possible, and no matter what the source of it the image will not be definite unless it is focused on the retina; and in order to be so focused it must be situated at the distance for which the eye is adjusted. In making the test, when we get to the point of reversal, we have the focus of the patient's eye at our own; and in order to have the light source focused on the patient's retina at the same time, it must be near the position of the surgeon's eye.

If you attempt to work closer than one meter, placing the light over the patient's head is not satisfactory. If you come to one-third of a meter there is one and one-half D. of inaccuracy, and that greatly lessens the value of the test. For many eyes the one-meter distance is fairly satisfactory, and if you take it as routine method the light above the patient will do. But if you limit your use of the test to this method, you restrict its value. A small point of light, too, is not satisfactory if placed over the patient's head, but if brought close to the mirror it gives a more delicate test.

I have used a disc, not one so well arranged and complete as this of Dr. Jennings. But after using it for some months I went back to the trial set. I prefer a small trial set kept right at hand. I find it, on the whole, more convenient than any form of instrument or disc.

Dr. H. V. WUERDEMANN of Milwaukee—The first instrument brought to this country was in 1887 by Donn of Oxford. In 1888 Burnett of Washington showed before this Section a disc skiascope, and about a year later I made a modification of it. Wood was the next man to put in an appearance with an instrument, which he uses with great satisfaction, based upon the same principles as those of Dr. Jennings. I would personally object to the size of this instrument on account of the space it would take up in the dark room, and in the examination more time is taken than is necessary.

Dr. J. E. JENNINGS—I think the idea of an extra piece of glass behind the mirror, suggested by Dr. Jackson, will be a very convenient thing, and we can thus keep the glass perfectly clean without rubbing off the silver. In regard to Dr. Würdemann's remarks, the hand skiascope is a very convenient and useful instrument, but an objection to it is that the patient controls the movement of the instrument and you are not always sure which aperture they are looking through, whereas my instrument records the number of the lens in front of the sight-hole and is under the control of the surgeon.

A METHOD OF EMPLOYING KANGAROO TENDON IN THE OPERATION FOR SHORTENING OCULAR MUSCLES.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY JOHN O. McREYNOLDS, B.Sc., M.D.
DALLAS, TEXAS.

Without attempting to review the subject of muscle shortening I will briefly present a method which has been quite satisfactory in my experience on account of the short time required for its performance, its freedom from pain, and the accuracy with which any degree of heterophoria may be corrected. It may also be successfully employed as an auxiliary in those cases of marked strabismus in which complete tenotomies alone will not entirely correct the deviation. The method is as follows: With broad fixation forceps pro-

vided with teeth sufficiently long to engage all the ocular tissues down to the sclera, grasp conjunctiva, capsule of Tenon and tendon of ocular muscle in such a way as to produce a loop of tendon. Then fix the loop thus formed by a single suture of kangaroo tendon embracing the ocular tendon. Tie the thread thus employed and leave it to be absorbed. In case there should be a desire to have the kangaroo tendon buried beneath the conjunctiva short incisions through this membrane will allow the thread to sink out of sight beneath the conjunctiva. The operation can be made in less time than one minute, involves no pain or subsequent discomfort and will correct with precision any ordinary degree of heterophoria.

A NEW OPHTHALMOSCOPE.

Presented in the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN WELSH CROSKY, M.D.

ATTENDING SURGEON TO THE WILLS HOSPITAL.
PHILADELPHIA, PA.

In the construction of this ophthalmoscope the object desired is to obtain a sufficiently large series of lenses in the most compact form and to permit of all the lenses being used without removing the instrument from the face.

When it is taken into consideration that to use an ophthalmoscope properly the accommodation should be relaxed, these advantages will be appreciated. The size of the instrument can be judged from the illustrations, which are two-thirds actual size, a point which will be valued by oculists who carry their ophthalmoscopes with them.

The ophthalmoscope itself consists of two discs, one for convenience called the lower disc, containing the weaker plus and minus glasses, ranging from + 1 to + 6 by single diopters and from - 1 to - 8 by single diopters; the upper disc containing the stronger lenses, ranging from + 8 to + 20 by alternate diopters and from - 10 to - 24 by alternate diopters.

It will be noticed that the discs are used independently and should the fundus require a stronger lens to explore it than is contained in the lower disc, it is not necessary to remove the ophthalmoscope from the eye; but, by simply pushing the mirror upward with the forefinger, so as to be opposite the lenses in the upper disk, as shown by the dotted lines in the illustration, the examination may be continued.

The sight-hole in the mirror is two millimeters in diameter, as it is found that a small sight-hole permits of a more satisfactory examination of the fundus through a small pupil.

A NEW OPHTHALMOSCOPE.

Presented in the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. L. BORSCH, M.D.

PARIS, FRANCE.

In this instrument the first noticeable feature is the construction and placing of the mirror: this not only tilts but also revolves about its own axis. The second feature is that the body of the instrument is so constructed that it can be revolved around its own axis carrying the mirror with it. This gives the mirror a third motion, first, tilting; second, revolving around its own axis; third, revolving around the axis of the body of the instrument, whereby the user can place the mirror at any desired position while the arrangement of the lenses remain undisturbed.

There are two lens discs effectually covered and protected from dust and handling, one containing the following lenses: 1; 2; 3; 4; 5; 6; 7; 8; 9; 10; 11; 12 convex. and 0.50 and 13 concave. The other disc contain: 1; 2; 3; 4; 5; 6; 7; 8; 9; 10; 11; 12 concave and 0.50 and 13 convex.

These combined produce seventy-six numbers as follows: 0.50; 1; 1.50; 2; 2.50; 3; 3.50; 4; 4.50; 5; 5.50; 6; 6.50; 7; 7.50; 8; 8.50; 9; 9.50; 10; 10.50; 11; 11.50; 12; 12.50; 13; 14; 15; 16; 17; 18; 19; 20; 21; 22; 23; 24; 25 both in concave and convex.

The second ophthalmoscope has the same arrangement of the mirror, viz., tilting and two rotary motions, only there is but one disc and a quadrant. The former contain the following lenses: 1; 2; 3; 4; 5; 6; 7; 8 concave and 1; 2; 3; 4; 5; 6; 7 convex, while the latter contains 0.50 and 16 concave, and 0.50 and 16 convex. The disc and quadrant combined produce the following numbers: 0.50; 1; 1.50; 2; 2.50; 3; 3.50; 4; 4.50; 5; 5.50; 6; 6.50; 7; 7.50; 8; 8.50; 9; 10; 11; 12; 13; 14; 15; 16; 17; 18; 19; 20; 21; 22; 23; 24 concave and 0.50, 1; 1.50; 2; 2.50; 3; 3.50; 4; 4.50; 5; 5.50; 6; 6.50; 7; 7.50; 8; 9; 10; 11; 12; 13; 14; 15; 16; 17; 18; 19; 20; 21; 22; 23; producing sixty-four (64) numbers in all, the same as produced by the Loring ophthalmoscope.

55 Rue Cherché Midi.

ANTINOSIN IN THE TREATMENT OF DISEASES OF THE EYE AND EAR.

BY W. FRANKLIN COLEMAN, M.D.

PROFESSOR OF OPHTHALMOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL, CHICAGO, ILL.

For some time I have felt the need of an antiseptic remedy which would be efficient, and non-irritating to the eye. While formalin is one of our best, if not the best of antiseptics, a solution of even 1 to 5,000 causes considerable pain. The action of sublimate is very superficial, and clinically unsatisfactory. Boric acid and iodoform are only very slightly antiseptic. I have also desired to get some of the properties of iodine, the tincture of which is well known to be curative when applied to ulcus corneæ; on account of its irritative effects its usefulness is very limited.

I have recently used antinosin in a considerable number of cases (both in my private and clinical prac-

tice) of catarrhal, palpebral and follicular conjunctivitis, phlyctenulae, ulcus corneæ, blepharitis marginalis, and also in otitis media purulenta. In a 1 to 2 per cent. solution it does not cause pain in the eye or ear, the patient rarely complaining of any unpleasant sensation. Antinosin is the sodium salt of tetra-iodo-phenol-phthalein. It is a dark blue amorphous powder, readily soluble in water and alcohol, odorless, non-toxic and non-irritant. It makes a purplish solution in water. The stain caused by very strong solutions can be readily removed by washing.

I refer to a few cases taken at random, which were treated by antinosin:

Case 1.—A. G., aged 48 years, had been treated for a long period on account of trachoma. The palpebral conjunctiva was smooth, but the patient complained of great sensibility to light and inability to read. Various applications were used, such as boric acid powder and massage, red oxid of mercury and massage, weak solutions of nitrate of silver, etc. These afforded very slight relief. A 1 per cent. solution of antinosin dropped in the eyes, t.i.d., afforded him in a few weeks, comparative comfort, relieved the photophobia and enabled him to do a moderate amount of reading. It also acted promptly in relieving several attacks of recurring ulcers of the cornea.

Case 2.—Miss G. B., aged 8 years. A case of long standing phlyctenular conjunctivitis, accompanied by intense photophobia. After using several of the classical remedies with very slow improvement, recovery was very much hastened by a collyrium of antinosin, 1 per cent. t.i.d.

Case 3.—J. H. D., aged 24 years. Palpebral conjunctivitis. The conjunctiva presents a velvety surface. There is also a blepharitis marginalis. There is a history of inflamed eyes for past five years, during which time medicine had afforded him little relief. A quarter of a diopter of astigmatism in each eye was corrected; the red oxid ointment, and argentum nitrate, 2 per cent. were applied for a month with little improvement. Under the use of antinosin, t.i.d., and massage, the case went on to recovery in a few weeks.

Case 4.—J. R., aged 34 years. History: Eyes have always been weak and inflamed. There is follicular conjunctivitis of the reflex folds and palpebral conjunctivitis, the ocular conjunctiva much injected. Glasses were prescribed, nitrate of silver, 2 per cent., applied on alternate days for one month, and tincture of iodine 1, to 3 per cent. of glycerin proved to be too painful for application to lids. Antinosin, 2 per cent., was applied t.i.d., and massage to lids once a day. In three weeks the eyes had very much improved and much more satisfactorily than under previous treatment.

Case 5.—Mrs. K., aged 71 years, has chronic palpebral conjunctivitis, for which I had previously treated her with the red oxid of mercury ointment and powdered boric acid and massage alternately, with a satisfactory result. A relapse occurred and antinosin, 2 per cent., and massage, were used daily for ten days, and the recovery was more rapid and complete than under previous treatment.

Case 6.—W. C., aged 40 years, complains of inflammation of the eyes for the past two years, which has been particularly troublesome for the past three months. There is palpebral conjunctivitis in both eyes and tarsal tumors of the right upper lid. Treatment: Tumors removed and curetted; antinosin 3 per cent. applied. Repeat antinosin, 1 per cent. t.i.d. After two months' treatment the lids were normal.

Case 7.—Miss S., aged 40 years, seamstress. Eyes have been inflamed off and on for six years past. The bulbar conjunctiva is much injected; chronic palpebral conjunctivitis. Palpebral conjunctiva is very red but smooth. Glasses were prescribed, and antinosin, 3 per cent. In three weeks the lids and eyes were much improved but still inflamed.

Case 8.—K. T., aged 4 years, when two years of age had a left mastoid abscess, for which an operation was performed by a surgeon. During the past week there has been otitis media purulenta of the right ear, and swelling over the left mastoid at the site of the previous operation. The swelling fluctuates on pressure and is exquisitely sensitive. Diagnosis: Mastoid caries and abscess. Incision was made and sequestrum and caries were found in the antrum, which was thoroughly curetted down to the dura. The wound was packed and covered with nosophen gauze, and bandaged. The right ear was treated with hydrogen peroxid and 2 per cent. antinosin and Politzerization daily. In six weeks the discharge had completely ceased in the right ear, and hearing improved from loud voice close to ear, to whisper at twenty feet. The left mastoid completely

healed, and the hearing of left ear improved to ordinary conversation at ten feet. The general health is better than it has been during the past year.

Many other eye and ear cases have been treated with good results, but these few suffice for illustration.

SOCIETY PROCEEDINGS.

Chicago Ophthalmological and Otological Society.

Regular meeting held Dec. 11, 1897, in the Stewart Building.

Dr. MONTGOMERY in the chair.

There were thirty visitors and members in attendance.

The minutes of the previous meeting were approved.

The applications of Drs. J. F. Fulton of St. Paul, Minn., Frank Allport and Wm. L. Ballenger of Chicago, were referred to the Committee on Membership.

On motion of Dr. Starkey, a committee consisting of Drs. Gradle, Starkey and Wilder, was appointed to confer with the editors of the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* and the *Ophthalmic Record* as to the publication of the minutes.

Dr. STARKEY opened a discussion on the

USE OF X-RAYS IN OPHTHALMOLOGY,

as follows: We all know that certain substances which are transparent, or nearly so, to ordinary light, are opaque to the X-rays, and *per contra* certain substances opaque to ordinary light are more or less transparent to the X-ray. In general, it may be said that the greater the density of the object, the greater its opacity to the X-ray, and it may also be said that the higher the vacuum tube the more transparent are bodies to the X-ray. Starting with this knowledge we can readily see that pieces of metal will cause a denser shade from the X-ray than bones, if a sufficiently high vacuum is used.

As far as I am aware, the case I shall report is the first one ever successfully skiagraphed in Chicago as to the location of a foreign body in the eye. It can be seen that it is necessary in the majority of instances that the skiagraph should be taken from two positions, from the side of the head and from the front, and by means of these two skiagraphs the body can often be definitely located. Dr. Sweet of Philadelphia has invented a plate holder and indicator which I had hoped to show, but am not able to do so. The tube now used is one made by the Queen Company, which overcomes the difficulty of getting a proper vacuum. This tube is arranged with a chemical and a shunt which controls the vacuum.

The first patient is a male 31 years of age, who was struck in the left eye on June 28 with a piece of metal. He was seen the next day, when the lens was found opaque so that nothing could be seen within the eye. The eye quieted down and he was discharged from the hospital, but in August the eye began to soften and it appeared that it was going to be destroyed. On August 20 a skiagraph was taken and it showed definitely that he had a large piece of metal in the eye. An attempt was made to extract the bit of iron with a strong electromagnet, but was unsuccessful, and the eye was removed.

The second case was seen October 28, male, struck in the eye with a piece of metal. A hole in the cornea, and iris and lens opaque. The next morning a skiagraph was taken, which showed the presence of a foreign body in the eye. An unsuccessful attempt was made to remove the steel, although it was only forty-eight hours after the accident. The eye was removed and a piece of steel imbedded in the blood clot, so that a magnet could not affect it much.

Dr. Starkey showed many interesting skiagraphs of the bones of the head and of foreign bodies in different parts of the body.

DISCUSSION.

Dr. CASEY A. WOOD—My experience has been very disappointing with the X-ray. Two or three weeks ago a man appeared in my office with, presumably, a foreign body in his eye, but the patient refused to have a skiagraph taken because he feared untoward results. It certainly looks as if with improved methods and short exposures we may expect some benefit from the use of the X-ray in ophthalmology in the future.

Dr. HALE—My experience, which is limited to one case, has been very disappointing, but I am also inclined to think that it was due to imperfect apparatus.

Dr. STARKEY, in closing, said that the exposure is never longer than eight minutes with the proper vacuum tube.

Dr. K. K. WHELOCK of Fort Wayne, Ind., read a paper entitled

TROPHO-NEUROTIC KERATITIS.

My attention was first called to this class of cases in March, 1887, when A. F. K., aged 55 years, a farmer by occupation and German by birth, consulted me with an attack of herpes zoster ophthalmicus of the right eye. The following I transcribe from my note book: Large ulcer on cornea at upper, inner segment; excavation shallow. Patient complains of a cold sensation in the eyeball as though the eye were a ball of ice. Anterior chamber one-fourth filled with pus, and iris bound down to capsule of lens leaving pupil the size of a pin-head. Patient a strong, healthy man, but pain had reduced him very much. The most complaint was on account of a sensation of continuous cold in eyeball. Ulcerative area had extended at next visit. The entire cornea is anesthetic. Faradization is used, and the cornea subsequently tested, when the sensibility is found to have returned. At next visit corneal sensation diminished. Faradization again employed. After fourth seance with faradization sensation remained in nearly normal state. Current had been applied from five to seven minutes over closed lids. There seemed to be no difference which pole was applied to neck. When sensation began to return to cornea the ulcer began to diminish in extent and depth. Ulcer did not penetrate into anterior chamber, and got well with an eschar. Three points in this case impressed my mind. 1. The diagnostic significance of corneal sensibility. 2. The value of faradization in such cases as presented sub-normal corneal sensation. 3. The pathology of herpes zoster ophthalmicus centering in the Gasserian ganglion. After this I gave much attention to testing corneal sensibility.

In January, 1889, Charles F. K., aged 39 years, German, machinist, was referred to me by Dr. M. F. Porter of Fort Wayne, with the statement that patient had gotten some sand in his right eye while engaged in his work. The notable features were slight lachrymation, very slight photophobia, no pain; simply a sense of irritation. Inspection showed a scarcely perceptible injection at sclerocorneal junction, no foreign body on cornea or conjunctival surface. The upper outer segment of the cornea was roughened as though it had been picked in many places with a minute sharp needle. The statement of the physician that the eye looked as if it had received a "sand blast" could be readily credited, only there was no history of such an accident. I tested the cornea with a spill of cotton, twisted hard, and found the cornea practically insensible over the area of roughening, while over the unaffected five-sixths of the cornea the sensibility was noticeable, but very much reduced, the reflex being lost: T. minus, pupil contracted. Treatment continued about one month. On February 19 notes show that the corneal reflex had returned. T. 2, and the roughened area was smaller in extent and less marked in point of apparent roughness. Treatment had been strychnia, quinin and arsenic and electricity systemically, while locally the usual cleansing solutions were applied. On June 23, 1893, Dr. T. J. Dills, then my partner, enucleated this eye, which is here submitted.

Dec. 4, 1895, Henry L., aged 55 years, farmer by occupation, German, consulted me with the following history: Four weeks before while hauling corn fodder from the field the wind carried something into his left eye. He had some pain at the time, and had to rub the eye and, for further relief, used chamomile poultices, which relieved him of the severe pain. He has suffered from occasional attacks of neuralgia of head for years. The last attack of neuralgia was ushered in by a chill, but he had no return of the chill.

He never suffered from digestive disturbance, but has suffered much from head pain, which always began over left eye. Years ago the pain would last for two or three days, but latterly it would pass off after a sleep of half an hour. Examination showed R. E. S. ^{20/20}; L. E. S. fingers at four feet, slight injection of sclerotic; cornea rough over outer third and center; reflex abolished as shown by touching with cotton spill; T. minus; cornea looked as though fine sand had been dusted over it. Under strychnia, arsenic and quinin, hot fomentations and boracic acid for a period of ten weeks, he recovered with perfect sight and only a fine nebulous eschar.

February 15, 1897, E. F. C., aged 31 years, electric engineer, consulted me for the purpose of having a foreign body removed from right eye. He had already visited an experienced ophthalmologist, in Pittsburgh, who informed him that there was a solution of continuity on the cornea, but no foreign body was present. A drop of cocain was employed and patient went about his work of inspecting some mechanical devices in the city. He did not note the irritation again till next morning, when he arrived at Fort Wayne. He then called at my office. Inspection showed no injection at sclerocorneal junction. Very slight photophobia; pupil contracted; a roughening of epithelium at inner upper quadrant; T. clearly minus 1; no sensa-

tion over roughened area and practical abolition of corneal reflex when tested over remaining clear corneal area. With the glasses which he was wearing: R. E. S. 20_{40} ; L. E. S. 20_{15} . Under treatment with strychnia hypodermically, faradization and hot compresses, he recovered in twelve or thirteen weeks. His functional examination showed R. E. S. 20_{70} ; + 4 D. 20_{30} ; L. E. S. 20_{30} ; + 4 D. 20_{20} ; hyperphoria 2° which had already been corrected by prisms.

Another case is characteristic of these three and I will omit details.

The second case detailed and the first of trophoneurotic keratitis series passed out of my hands because my acquaintance with the prognosis was not sufficient to establish either a maximum or a minimum time during which treatment must be carried on. The enucleation of the eye by my partner, Dr. T. J. Dills, recalled the history of the case. The series presents the following features common to all: Loss of sensation in area of corneal involvement; subnormal sensibility; not total loss of secretion over area of unaffected cornea and abolition of corneal reflex; tension variable, but always minus; contracted pupil; slight pain, if any; slight irritation and then always as though a foreign body were in the eye; little or no circumcorneal injection. The time over which active therapeutic measures should be employed is ten to fourteen weeks. These cases have all gotten well with good vision and a very slight nebulous eschar.

The name trophoneurotic keratitis is distinctive and should be adopted for the class of cases which I have described, because the name is significant of the organs involved and points to the trophic fibres of the Gasserian ganglion as the seat of lesion. The name "neuroparalytic" should be abandoned, except in cases where gross lesion of the brain is present, or the ganglion is involved *en masse*, or when, in the presence of evident involvement of the trophic fibers, there is also a general lesion of the entire ganglion, as shown by loss of sensation throughout the whole distribution of the fifth nerve. Such a case as referred to in the last division I have seen as a result of periostitis of the petrous portion of the temporal bone and due to inherited syphilis. The case was that of a little girl, 10 years old, in which the trouble was symmetric. But only the right cornea had undergone central ulceration with perforation. In this case so profound was the anesthesia that a tooth had been extracted without pain, and the incident was referred to as indicating great heroism on the part of the little patient. Trophoneurotic keratitis differs in its pathology from keratitis e lagophthalmo in that in the latter condition the lesion of the cornea is the result of exposure from an uncovered cornea together with general loss of resistance on part of all the tissues. In trophoneurotic keratitis the lesion is found under the covered cornea. Snellen's theory of exposure and mechanical irritation is not tenable in this class of cases. We must also differentiate from keratitis malacia. We have all seen cases of hemi-anesthesia of the face in which there has been no desiccation or ulceration of the cornea. I am disposed to think that the sympathetic fibers supplying the Gasserian ganglion play a very important role in the nutrition of the cornea. The cases which Noyes refers to as "superficial keratitis" of malarial origin have all the earmarks of the cases which I have described, and he, together with all authors, including Von Graefe, has failed to distinguish between the gross involvement of the ganglion and the involvement of the trophic fibers alone. Von Graefe described those cases but did not recognize the influence of the trophic fibers. De Schweinitz in "Diseases of the Eye," last edition, describes the trophic and neuroparalytic form, and causally groups them under "neuroparalytic" disturbances of the cornea. Fuchs, in his admirable work, refers to the probable trophic origin of certain corneal ulcers. Schmidt Rimpler in his third German edition of "Ophthalmology and Ophthalmoscopy," translated by Roosa, comes very nearly to the exact truth in his opening sentence on the subject of keratitis neuroparalytica. He says: "The form of keratitis which develops in paralysis of the trigeminus may correspond entirely to the neurotic form in its appearance and course." Finally, Meisner and Schiff have shown experimentally that the characteristic inflammation known as keratitis trophoneurotica occurs when the central fibers of the Gasserian ganglion are divided.

In case of paralysis of seventh when the cornea is not covered or even swept except by extreme contraction of superior rectus and inferior oblique we yet have no evidence of desiccation.

DISCUSSION.

Dr. WILDER—I have a case just recovering which has been under treatment for fifteen weeks, a case of obstinate superficial ulceration of the cornea, gradually involving the whole surface. Everything I could think of has been tried, cauterization with

nitrate of silver, carbolic acid and galvano-cautery, and the only relief given him was by applying absolute alcohol. This case is probably one such as the author speaks of. Possibly all such cases are in a sense dependent upon some lesion of the trophic centers rather than of the trophic nerves in the Gasserian ganglion. The cause may be malarial poisoning, in which case the ulcers would assume the peculiar dendritic form. All such cases resemble and are often associated with herpetic efflorescences in other places, and should be distinguished from true herpes zoster, which is a more serious affection. A point of interest which the Doctor brings out is the diminution of sensation.

Dr. COLEMAN—I rise to mention one method of treatment to relieve the pain. In two recent cases in which the corneal ulceration was a part of an attack of herpes zoster the intense pain was relieved, but only temporarily, by large doses of chloral, morphin and quini, but it was permanently relieved by sodium salicylate.

Dr. GRADLE—I wish to call attention to the sharp distinction that there really is between ordinary herpes and herpes zoster. The dendritic form, as mentioned by Dr. Wilder, can begin as corneal herpes, and I have seen two such cases this year. In these cases there is no diminution in sensibility. I have seen two instances of corneal involvement in the course of herpes zoster, but in neither case was the ulceration quite as important as the keratitis, which was diffuse. Many of these cases are followed by very serious consequences. One of my cases was followed by paralysis of the rectus muscle. The question of the influence of trophic nerves on the cornea is open to doubt; in fact, the nerves themselves are not proven, and it is still in doubt whether the keratitis arises from a disturbance of nutrition or from the presence of foreign bodies.

Dr. PINCKARD—The paper reminds me of a case I now have under treatment, which while not neuroparalytic, perhaps resembles such cases in some respects. Some four weeks ago I was called to see a lady about 70 years old who had an herpetic eruption on the outer part of the upper lid. There was marked edema of both lids and conjunctiva, accompanied with redness and considerable pain. Later there appeared herpes on the side of the nose and temple. My fears were for the cornea, which I carefully watched. A curious change took place. The whole corneal surface became hazy, the haze being more marked at the periphery, not in the center. At the same time the cornea became anesthetic. There was and is still some circumcorneal injection, but it is not very great. There has been no pain in the eye, nor has a vesicle formed on the eye. It seems to me that this condition is a true neuropathic keratitis, whether paralytic or not it is hard to say. The herpetic spots on the face have healed, but no change has taken place in the cornea.

HOLOCAIN.

Dr. HOTZ—At our meeting in October I read a brief report of my observations with holocain. Dr. Würdemann wrote me that his experience had been somewhat different, and suggested that we bring up the matter for discussion at this meeting. At the October meeting I stated that holocain was a very prompt, quick-acting anesthetic, but seemed to me not to penetrate deep enough to make it of value for more extensive and deeper operations, especially one involving the opening of the eyeball. Since that time I have used the remedy considerably and the results are about the same.

Dr. WÜRDEMANN followed Dr. Hotz in the discussion and said: "Würdemann and Black have used holocain successfully in the following cases: Six cataract (simple) extractions, three cataract extractions with iridectomies, three cataract discissions, six iridectomies, eleven tenotomies, three tenotomies with advancement, six canaliculotomies, four chalazia, one sarcoma of conjunctival limbus, one pterygium, one curettement of corneal ulcer, two cauterizations of corneal ulcer, a number of foreign bodies in conjunctiva and cornea, as an instillation before the use of irritating medicines such as silver, bluestone, alum, iodine, etc., and direct application of electrode to corneal and conjunctival surfaces. The anesthetic qualities of holocain equal those of cocain, are no more irritant and excel cocain for operations on the bulb in the following: Its action is quicker and more lasting; it more thoroughly anesthetizes the iris and deeper structures. It more thoroughly anesthetizes inflamed surfaces; the anesthesia may be indefinitely prolonged; the cornea does not desiccate under its use; it does not affect the tension; it does not act on the pupil or accommodation; it does not interfere with the nutrition of the tissues but rather increases their blood supply and hastens healing; its solutions are antiseptic; it is already proportionately cheaper. The only disadvantage in the substitution of holocain for cocain for anesthetic purposes is that bleeding is more free under holocain. Although holocain possesses these

distinct advantages over cocain when applied as a pure anesthetic, it has not and probably will not entirely supersede the older medicament.

Dr. Hertz—I can not quite understand on what ground Dr. Würdemann claims that the absorption of holocain is better than that of cocain. If I am correct, the absorption is a sort of osmotic process and has nothing to do with the circulation. We know that cocain combined with atropin is often more readily absorbed than atropin alone, so that cocain seems to increase the absorption. The pain from the application of holocain is most intense in a 1 per cent. solution and the after-effects last for hours. One great advantage of the drug is that it will keep and does not undergo any chemic or bacteriologic change.

On motion the Society adjourned.

C. P. PINCKARD,
Secretary.

Chicago Academy of Medicine.

(Concluded from page 219.)

Regular Meeting, Nov. 12, 1897.

A. E. BALDWIN, M.D., in the Chair.

CHOICE OF OPERATION IN AMPUTATIONS AT THE KNEE JOINT.

Dr. J. B. MURPHY—The technique of the operation is not so difficult and requires very much less consideration than the points brought out by the preceding speaker, namely, the position of the scar after the operation, and the ability of the patient to wear with comfort an artificial limb. These are the important facts. Here amputations for the purpose of using the stump for pressure, can be made only where we retain a portion of the leg and knee joint the same as we retain the posterior aspect of the os calcis in operations on the foot, or where we produce talipes equinus in an exaggerated degree by resecting a portion of the foot and producing osteal union between the portion of the foot preserved and the tibia. These points can all give support when pressure is brought upon the stump. Pirogoff's operation is the ideal amputation of this character, as it so arranges the stump as to carry the weight of the body on the dense tissues of the heel. It is well known that when we produce a talipes equinus of extreme degree, the limb is not capable of carrying the weight of the body so well, and the patient subsequently suffers a great deal of discomfort. As to the line of amputation, I have always felt that amputations through the knee joint was much more serious than one above or below the joint; that is, making a knee-joint amputation, retaining the articular surface with or without patella, is a much more serious matter than amputating the leg above the articulation. When it is made above the knee joint I feel that we should select a position where the bone is about the normal size of the shaft of the femur; that is, we should go two and a half inches above the articular surface, so that we remove at the time of the amputation the flanging enlargement of the lower end of the femur. Then we have a stump to which we can attach an artificial limb without any difficulty; the pressure with an artificial limb does not come on the end of the stump but more on the side, except in the cases above mentioned. Now comes the question, how shall we make the line of incision so as to relieve the cicatrix from pressure and irritation? Furthermore, how shall we make the incision in the skin and superficial muscles? How shall we make the incision in the deeper muscles and periosteum? If we make it in the same line, when we have union we will have a scar direct to the bone and the patient will suffer from periosteal irritation. If we amputate the limb through the condyles we can not make a periosteal flap to cover the end of the bone. It is impossible to preserve periosteum in that position; it therefore can not be brought over the flanging end of the bone. In order to cover the end of the bone with periosteum we must remove it above the expanding portion of the femur; one of the desirable methods in amputations in any position where there will be pressure on the end or side is to cover the bone with periosteum. True, when we make an amputation through the condyles and preserve the patella, taking off its articular surface and placing it in a position to secure osteal union between the patella and shaft of the femur, we compensate to a certain extent for the preservation of the periosteum. Now, then, the line of incision must be such that when the tissues are approximated, the scar will occupy the position where there is the least friction and pressure. If we make the amputation in the thigh I am very much in favor of a circular flap. I have always used it, as there is less likelihood of having a continuous cicatricial mass to the periosteum. If we adopt the plan of suturing the subcutaneous tissues, muscles, sheaths, etc., in layers over the end of the stump, the muscles will eventually be absorbed by pressure, but before absorption takes place they prevent

adhesion of the superficial scar with the periosteal scar, and in this way allow movable tissue on the end of the stump which is not fastened to the end of the bone.

The method of taking care of blood vessels on account of danger from secondary hemorrhage is one of considerable importance. The experiments of Dr. Senn showed that when we put on a double ligature we had much less likelihood of secondary hemorrhage than from a single ligature. This, I believe, was due to the fact that the upper ligature was not placed as firmly as the lower, and a clot was formed between them. I found in the practical application of that method that it is difficult to say how much pressure we need upon the ligature. If we will change the method of ligation of vessels we can obviate the necessity of a double ligature entirely. When we ligate an artery, draw it down with forceps. Do not ligate an artery on the proximal side of the forceps, but put the forceps high up on the vessel and ligate on its distal side. By ligating in this way we are sure to injure the intima with the forceps. If we injure the intima in the position where the circulation is intact, that is, where there is a continuous circulation of blood, immediately after the injury we have the formation of a clot which fills that portion of the vessel and becomes firmly adherent to the injured intima. This method was deduced and demonstrated in our recent arterial experiments. I have found that we have the safest guard against secondary hemorrhage in an artery that has its intima injured the most on the proximal side of the definite ligature. If we injure its coat by the application of forceps we produce thrombosis. The nerve should be drawn down and divided so that it will not be involved in the scar. I speak now, of course, of the large nerve in that region. By so doing we lessen the liability to neuroma from involvement of the nerves in the scar. If the sheath of the muscle be split and the nerve be inserted into the muscle there is less tendency to neuroma.

We have therefore in the operation itself, 1, the line of incision; 2, the protection of the end of the bone with periosteum to prevent adhesion at the line of incision of the superficial parts to the end of the bone; 3, care of the artery so as to produce injury to its intima and thereby bring about a primary thrombosis after the completion of the operation; 4, care of the nerve, and 5, drainage.

I believe that we have drifted too far from drainage in recent years. Surgeons take a great deal of pride in saying that they have never found it necessary to drain their cases. It is a very nice thing to say. When members of this class find it necessary to drain secondarily, they generally lose the patient. We must always be on the side of caution, and I believe that forty-eight hours drainage does not in the least retard primary union. Drainage for this length of time removes the primary wound secretion which prevents the accurate apposition of living tissues. Primary wound secretion can be nothing less than a detriment to union. Drainage for this length of time brings about accurate apposition. What else? The karyokinetic changes are taking place within a short distance of the cut surface and are preparing for a definite union.

INDICATIONS FOR AMPUTATION ABOUT THE KNEE JOINT.

Dr. ALEX. H. FERGUSON—The indications for operations about the knee joint have changed from time to time as science has advanced. The invention of the tourniquet, the ligation of arteries, the discovery of anesthesia, and the introduction of aseptic and antiseptic surgery have each added to or subtracted from the indications of these operations. There is no subject in the whole range of surgery that has been more talked about, more thrashed out and discussed, than amputations in general by the ablest surgeons of all times. And since the days of antiseptics and exploration of new fields, some physicians imagine that no advance has been made in amputations of extremities in the last twenty-five or thirty years. But such is not the case. One would suppose by this time that all the indications would have been really defined, but we are far from having all of them settled, and we can yet speak with propriety upon the various conditions which demand, and which do not demand, amputation. It varies a great deal with personal experience and with the conscientious ability of the surgeon to know what he can do in certain cases. To lay down a number of absolute indications for amputation at the knee joint would be folly. The indications, however, that are brought prominently before us are those produced by injuries. We may classify these injuries into mechanical, chemical, electrical and thermal. Mechanical injuries are the most common. There is no doubt about the necessity for amputation at the knee joint when the limb is torn away and totally destroyed below the joint, in a railroad accident, by machinery, or by a cannon ball sweeping along and taking it away. The indications in such cases are clear for a speedy amputation in the manner

described this evening. Incised wounds, punctured wounds, lacerated wounds implicating the knee joint itself used to be frequent indications for amputation above the knee joint, not so much on account of the injury *per se*, but owing to the inflammatory conditions which followed, causing a septic arthritis. It was noted by the older surgeons that a large tear into the knee joint was much less dangerous than a small puncture. It is quite clear that a puncture would carry infection, and if not counteracted, eventually an amputation might be necessary. When, however, drainage was free, or the infection slight, a number of cases escaped amputation. All minor injuries, if taken hold of early and properly treated, are now excluded as cases for amputation above the knee joint. When the knee joint is involved we render the part aseptic, use antiseptics, and, if necessary, operate and do away, as much as possible, with the probability of septic inflammation following, but still there are some cases that have been neglected either by the patients themselves, or through an oversight on the part of the practitioner; septic arthritis from apparently minor injuries to the knee joint demands amputation. But not all of them. Even in those septic cases, if we freely open the joint, and, if necessary, lay it completely bare from one side to the other, use antiseptics and establish free drainage, a number of them go on to recovery without requiring amputation. It is a notable experience that excisions at the knee joint for acute septic arthritis are very fatal, and they are practically discarded. If we can not save a joint by free drainage, asepsis and antiseptics, we have to amputate it.

The indication for amputation when a wound is poisoned may come before the surgeon occasionally, as, for instance, when the knee joint of a child is torn by a mad dog. The idea of amputating is the first thing that naturally arises in the surgeon's mind. But I do not put this down as positively a justifiable procedure in the light of our knowledge of hydrophobia and its treatment. The surgeon would be governed by the conditions and circumstances of the case.

Other indications for amputation would be those in which the knee joint is crushed, or the bones below it are so injured as to leave no hope of recovery of its tissues. In these cases amputation or disarticulation should be done. In cases of compound fracture implicating the knee joint, and compound dislocations involving it, it would depend more upon the injury done to the soft structures than the fact of these compound conditions existing as to whether we should resort to amputation or not. A knee joint may be saved although there is a compound comminuted fracture, or a compound dislocation of it, provided the structures in the popliteal space are all right, and sufficient of the soft tissues in front are left healthy and intact to cover in the joint.

I will pass over the chemical injuries to the knee joint and consider the thermal—those of heat and cold. When a limb is hopelessly destroyed by heat below the knee joint, I am rather inclined to do a primary amputation. If the injury is so extensive as to char the limb, there is no doubt but a primary amputation is indicated. We know from our experience with crushing injuries that shock will not often subside until after an amputation has been performed. The shock will not subside, sometimes, in thermal destruction of the limb, until the patient is put profoundly under anodynes. I remember amputating the two legs of a little girl whose feet were badly burned, where the shock did not begin to pass away until after she was put under the influence of an anesthetic.

With regard to cold. You all know that I came from a country where it was cold. I have seen the temperature range from 25 to 45 F. below zero for six weeks at a time. I remember of having as many as a dozen or more cases brought into the hospital suffering from the effects of cold, especially frozen extremities. I believe there is an indication for primary amputation in some of these cases where both feet are frozen up to near the knees, and hopelessly gone from the start. Lives can be saved by doing primary amputation within forty-eight hours in such cases. I know that I have saved the lives of one or two patients by so doing. I have in mind at present a man, shipwrecked on Lake Winnipeg, whose two legs were frozen to a little below the knees. We waited for reaction, which never came; we watched for a line of demarkation, which never took place, and the patient succumbed in spite of all our efforts. We kept the limbs as perfectly aseptic as could be, and still the case went on and developed septicemia, and died in a condition not unlike that found in acute traumatic gangrene. In less extensive gangrene from frost bites the rule is to wait for a line of demarkation.

The electric destruction of limbs needs only to be mentioned as an occasional indication for amputations about the knee joint. There are injuries to the popliteal vessels and nerves which call for amputation. Injury to the popliteal artery or

vein is occasionally present in separation of the epiphyses. I have met with two such cases. One case was that of a boy trying to climb into a wagon when suddenly the horse started, his foot slipped between the spokes causing separation of the epiphyses. When I was called to see him soon after the accident the limb was warm, but the artery was completely ruptured and we had to do an amputation the next day. It appears that in nearly all cases of separation of the epiphyses there is more or less injury to the vessels of the popliteal space.

Injuries to the nerves that demand amputation would be usually those of gunshot wounds, where a considerable portion of the nerves posterior to the knee joint would be destroyed. This brings us to the next class of indications, namely, diseases. The first would be inflammations, such as acute septic arthritis, which I have mentioned already. Then comes acute osteomyelitis. In a fracture near the knee joint acute osteomyelitis may start up, streptococcus infection may occur, and this may call for an amputation. Chronic osteomyelitis destroys the bones of the leg and suppurative may be so extensive that an amputation may be indicated in order to prevent general pyemia.

An important indication for amputations about the knee joint was tuberculosis, and for a long time knee-joint amputations were performed in almost all well pronounced cases of tuberculosis of the knee joint. That practice, however, subsided and excision of the knee joint was then introduced. Now we save many cases even from excision. There are certain conditions, however, in which amputation is still in vogue, and will be practiced as long as there is tuberculosis of the knee joint. I refer now to those cases of tuberculosis of the knee joint in which the patient has lung infection as well, where it is important to keep the patient in bed as short a time as possible. If the patient is run down constitutionally we can do quicker work by making an amputation, and can get a patient out of the hospital in two or three weeks thereafter. Amputation at the knee joint is indicated for tuberculosis when the joint is thoroughly destroyed, where the soft structures are all riddled with sinuses, and there is not sufficient bone left behind to make a suitable excision. In tubercular osteomyelitis involving the tibia up to near the knee joint, it is not necessary to amputate up to the line of extension of the disease. The infected part in the center of the bone can be scraped out and amputated at a suitable place.

Aneurysm of the popliteal artery sometimes demand amputation at the knee, those diffuse ones which rapidly spread and occlude the blood vessels so as to endanger the life of the limb below. In chronic aneurysms that extend into the knee joint, and in those not curable by other methods of treatment an amputation is advisable.

Sarcoma is a frequent indication for amputation. If we have sarcoma of the soft parts it may be removed. If it develops on the periosteum itself, and not too extensive, it may be chiseled off. I recall a case of sarcoma that I chiseled from the tibia over a year ago and followed it up with the antitoxin treatment from the streptococcus erysipilatosus and prodigiousus. There has been no return of the disease. Carcinoma is another indication for operation. It arises sometimes in connection with old chronic ulcers. Gangrene is one of the marked indications for amputation at the knee joint, and one of the most prominent indications demanding the operation is a spreading traumatic gangrene. If infection takes place in a severe injury below the knee joint and gangrene climbs up the limb, then amputation or disarticulation must be done at the knee joint, depending upon the condition of the soft structures. Gangrene spreads along the cellular tissues so rapidly that although the skin may look healthy when we cut it, we find we have to go higher. These cases often call for amputation above the knee joint. A good deal, of course, depends upon the time when we get the case and the extent of the gangrene. The symmetrical gangrene of Raynaud demands amputation. Diabetic gangrene is that form which surgeons formerly did not care to touch, but now with our aseptic and antiseptic precautions, in suitable cases we operate, knowing that diabetes *per se* is not the cause of such cases doing badly, but that the wound formerly did not heal on account of infection. We know now that these wounds do heal when suppuration is prevented. The diabetic condition serves as a predisposition for the multiplication of germs in the tissues. We also have senile gangrene to contend with in considering amputations at the knee joint. Amputation may be done at the knee joint in deformities, either congenital or acquired. We may have a tubercular or traumatic condition of the knee joint, which disables a patient for a long time. The limb becomes contracted, ankylosed and fixed in an abnormal position. Amputation may be a blessing in such cases. Congenital defects below the knee joint, in rare instances, call for amputation. In bad stumps due to disease of the bones, chronic ulcers, painful enlargement of the nerves,

etc., an amputation higher up is the only thing to do in order to remove the pathologic conditions and get a good useful limb.

Having spoken of indications, I desire now to say a few words in connection with amputations at the knee joint.

Amputation at the knee joint is a recognized modern surgical procedure on sound surgical basis. We make a distinction between disarticulation at the knee joint, and amputation through or above the condyles of the femur.

History.—Allow me to mention a few historic facts connected with this operation. The earliest notice of it is by Fabritius Hildanus, who performed it in 1581. It was revived by Hoin (1764), after a lapse of 183 years. In spite of strong support by some of the best surgeons of this time it was soon forgotten, and sixty-six years went by until the great surgeon, Velpeau (1830) took it up and made it popular.

In 1824 Dr. Nathan Smith amputated at the knee, and his operation was the first of the kind in America. In this connection he may be characterized as the "Velpeau" of America. Markoe, Pancoast, Brinton and others, also advocated the operation.

British surgeons have been alive to the benefits of amputation at the knee joint; among those giving it distinction were Holmes, Pollock, Cooper, Syme, Carden and still later Ferguson, Lister, Stokes and others. This operation has been practiced more in America than in any other country, and the bilateral method devised by Dr. Stephen Smith will for all time have a useful and permanent place.

Surgical anatomy.—The anatomy of the knee joint is peculiar. Large size, with ligaments, tendons, synovial pouches, bursa, large surface of articular cartilage, fibro-cartilages and tuberos bony extremities, all are encased in a strong fibrous sheath covered by skin. The quadriceps extensor tendon, the patella and the ligamentum patellæ are in front, each having its surgical bearing. On either side the hamstring tendons which demand our consideration, and behind in the popliteal space are situated the heads of the gastrocnemius, plantaris and popliteus muscles, as well as the vessels and nerves.

A brief consideration of the anatomy will show that the anterior 2/3 of the joint is but poorly supplied with blood vessels, and has no muscular tissue to form a good covering for the large head of the femur.

The tendons extending beyond the joint, to be attached to the tibia and fibula, retract so far when cut that it is difficult to utilize them in the flaps. If the anterior flap is too long its edge will inevitably necrose.

What shall we do with the patella? Should the condyles be cut off? How should the vessels, nerves and tendons be dealt with? What flap or flaps will obtain the safest and best results? These are the questions that surgeons have been trying to solve, and for which purpose many operative procedures have been carried out and recommended.

Operations.—Disarticulation may be diverse. 1. disarticulation by a short anterior and a long posterior flap (Hoin); 2, by a long anterior flap (Pollock); 3, by a long circular incision (Velpeau); 4, by an elliptical incision (Bauden); 5, by a modified circular (Chalot); 6, by lateral flaps (Stephen Smith).

Indeed these are not all the methods devised for disarticulation at the knee joint. Pancoast successfully made use of three flaps from the upper part of the leg. Which of these to select in a given case will depend largely upon the indications for the operation. If the case was one of injury below the knee, demanding disarticulation, the condition of the patient as well as that of the limb is to be taken into consideration. When shock is profound and continuous, as in a crushing injury, the life of the patient demands our first attention, and to save it rapid work must be executed. Dr. Stephen Smith's (1870) bilateral amputation can be done as quickly as any of the above six methods, and the stump is, I think, the best.

The recommendation of Dr. Brinton in 1872, to sever the semilunar fibro-cartilages from the tibia and leave them in the stump is a decided advantage. His own words are: "By thus leaving them in position I have a cap fitted upon the end of the femur which preserves all the fascial relations, eventually prevents retraction and guards against the projection of the condyles." The patella is of course left undisturbed, and it adds strength to the stump by preserving the integrity of the quadriceps extensor. The ligamentum patellæ should be cut close to its insertion. I am in the habit of cutting the hamstring tendons lower than the joint line and fastening them to the stump with catgut, in order to prevent their retraction and preserve their function. When a new and suitable insertion is given to these tendons, the strength and all the movements of the thigh are preserved, the stump can be as forcibly adducted, abducted, flexed, extended and circumducted as if no amputation had been performed. None of the authorities, and I must say none of the operators as far as I know, pay any attention

to the above-mentioned treatment of the tendons of the muscles.

This simple procedure of giving insertions to severed tendons is especially suitable in amputation about the hands and feet. The vessels are ligatured always with catgut. If silk is used, history almost surely repeats itself, and one silk ligature after the other comes away by a process of suppuration. A vast amount of suffering, inconvenience, and more or less damage to the stump (making it tender), are prevented by absolutely discarding the use of silk in all amputations of the extremities.

The nerves must be cut shorter than the structures, and if of considerable size as here, it is possibly better to remove a wedge-shaped piece from the end of each, as recommended by Senn and coapting the two little flaps with fine catgut. The object is to remove the cut nerves away from the scar and end of the stump, thus lessening the tendency to the formation of neuromata and painful stumps.

Disarticulation by Stephen Smith's method has many features to commend it. An excellent covering for the femur; efficient drainage; well nourished flaps; scar between and behind the condyles, and a stump, powerful and serviceable are obtained. I fully agree with Roswell Park in calling it "The method of election." The tissues may be injured in such a manner as to make it impossible to form lateral flaps, then the surgeon will of course make his flap or flaps from healthy tissues. It is gratifying to know that one long posterior flap may be all sufficient, or the circular or modified circular is all right.

Two even, or uneven flaps, from any side of the knee may be chosen in emergency.

In selecting a disarticulation the joint must be healthy, free from infection, disease or extensive injury; the surrounding skin and structures must be healthy to afford ample flaps. In disarticulations as compared with amputations of the femur, shock is much less and the rate of mortality is very much lower. Aseptic and antiseptic surgical precautions have done a great deal for this operation. According to Legouest the mortality of disarticulation at the knee joint was 87 per cent., and of amputation of the thigh 74 per cent. during pre-antiseptic times; while now, according to Erdman (1895), the mortality of disarticulation is only 13 per cent., and of thigh amputation 21.5 per cent.

Septic infection of the synovial membrane, cartilages and bursa, made the operation of disarticulation at the knee in former times simply a fearful one; hence the recommendation of amputation above the condyles by the older surgeons.

I am well aware that the surgeon who looks mainly to prosthesis would abandon the operation of disarticulation altogether, but he who pays attention to the principles of exeresis will stoutly uphold it.

Amputation through the condyles.—1. Transcondyloid (Carden's, 1846) (a) Lister's modification (1883), (Gross, 1866). 2. Gritti's osteoplastic operation (1857). 3. Stokes' supracondyloid modification of Gritti's (1886). 4. Sabanejeff's (of Odessa 1890) osteoplastic flap amputation.

Carden's operation consists of a long anterior skin flap, the length of the diameter, at the point of osseous section, and the dividing of everything else straight down to the bone, which is sawn through slightly above the plane of the muscles. Lister and Gross made a short posterior flap of skin, but otherwise the operation is just the same as Carden's. All the muscular and fibrous structures are sacrificed and the bone simply covered by skin.

I do not perform, as a matter of choice, any amputation which sacrifices all the muscular, tendinous and fibrous structures.

In Carden's amputation, the anterior flap is liable to die, the stump is easily injured and can not bear much weight on its end, and the whole stump is weak, because the muscles are allowed to retract, thus greatly losing their function.

In the light of our present knowledge of amputations and stumps, I can not understand why Carden's operation should be performed at all; it is much better to make the anterior flap a little shorter, and the posterior one longer; to preserve the quadriceps tendon to cover the bone, enucleate the patella if diseased, and if not saw a slice off it and leave the posterior muscular and tendinous structures sufficiently long to enable you to suture them to the deep fibrous structures of the anterior flap, when brought over to the end of the bone. In this manner, an ideal stump is the result. It is beautiful in shape, will bear the weight of the body on its end and is powerful in all its movements. By this means skin is sutured to skin, fascia to fascia, tendons secured in the stump, and all forming one uniform covering for the end of the bone.

When the operation is done for tubercular disease, all the synovial membrane should be dissected out. It is to be remembered that the condyles must be sawn through on a level with their terminations, and not at a right angle with shaft of the

bone. If a child or youth is the subject under treatment, the epiphyseal line should be respected, and not encroached upon, if possible, under 18 or 20 years of age. Efficient drainage is obtained by means of a few strands of silkworm gut. Gritti's operation is a good substitute for Stephen Smith's disarticulation, when the patient is in excellent condition constitutionally and when it is not necessary to make a speedy operation. It takes more time to saw, fit and suture the patella and femur together than to do a disarticulation. This is also true of Stokes' and Sabanejeff's operations. Not infrequently you begin with the intention of performing Gritti's; but the patella can not sometimes be brought over the end of the bone until slice after slice is removed, and the operation is completed as a Stokes' modification. Gritti's and Stokes' operations are especially suited for tuberculosis of the end of the femur, where an excision is not advisable. I have no experience with Sabanejeff's osteoplastic operation; it appears to be an operation that will be suitable in exceptional cases.

When a section of the anterior surface of the tibia, including the tubercle with its attached patellar tendon, is removed, as in this procedure, more healthy tissue is required below the knee than in all the preceding operations, which may be an objection to it.

TREATMENT OF PATELLA.

Dr. CARL BECK—I shall have to make a few remarks only in regard to the treatment of the patella, as so much has been said by Drs. Cuthbertson and Murphy. There is one point to be considered in connection with the treatment of the patella, namely, the pathologic condition for which we operate. If we have a trauma to deal with, conservatism prompts us to leave everything possible. We leave the semilunar cartilages and the patella, if they are not crushed, if possible, in order to give the stump greater mobility and prevent retraction of the muscles. In those cases where the disease has invaded the knee joint and amputation is necessary, usually the patella is diseased also, and is not to be left. In most of the cases of Gritti's or of Stokes' operation the bone itself may be so thin by osteoporosis, that agglutination and further on adherence and callus of the bone is almost impossible. This applies particularly to tuberculosis. When tuberculosis develops near the knee joint, osteal atrophy extends a considerable distance up from the joint, and the healing of such osteoporotic bones is not liable to occur. Therefore, in most cases in which I have seen Gritti's operation performed by Gussenbauer, a secondary amputation has been made later on account of a badly healed tubercular stump.

The Stokes operation is not so important for our discussion, for the reason that support in our time is not on the stump but on the pelvis, and the stump itself rests only in an artificial limb and is not very much pressed upon. So much for the treatment of the patella.

I wish to say a few words now with regard to the treatment of the nerve. In order to prevent neuralgia and the formation of amputation neuroma, it has occurred to me that it would be necessary not only to draw the nerve down, but to make a plastic operation on the nerve; that is, split the nerve, remove half of it, fold it over, etc. I have done this in two cases a short time ago. I am not able to give you the results just now. I intend to make experiments along this line to demonstrate the healing of the nerve, making a plastic operation on the nerve and reflecting it upon itself. It seems to me, this will prevent the formation of amputation neuroma. The neuromata are very painful. I have excised a number of them. I have seen Dr. Ferguson excise these bulb-like growths. I believe drawing down the nerve is of great value, but inasmuch as the nerve ends remain there by their own tendency to grow, they develop often, even if not enclosed in connective tissue, into bulb like growths, and this of itself may cause neuralgia. I have not had a chance to observe the cases for a long time, but I will report my experiments later in a special paper.

FORENSIC RELATIONS OF AMPUTATIONS AT THE KNEE JOINT.

Dr. HAROLD N. MOYER—So far as the consequences of amputations are concerned, litigation might arise on account of bad stumps. These are by no means infrequent, and so far as their application to the knee joint is concerned, I do not think they are any different from amputations made in other parts of the body. There is one special form of disarticulation at the knee joint which calls for some consideration on account of its medico-legal relations, namely, cases of children before the bone has reached its full growth. I have seen a number of such cases, which have been litigated in our courts in various ways, and one of them is so interesting a type, that I will briefly relate it.

A case that has recently come under my observation is instructive as to the possible complications that may arise from

a bad stump in children. Bryant in his excellent work says that conical or sugar-loaf stump is a natural consequence in children, that growth continues in the bone with greater rapidity than in the soft parts, and the end of the bone is thrust against the cicatrix in the flap and eventually adherence with painful conical stump is the result.

If this fact be lost sight of, it may lead to a suit for malpractice, as friends and relatives are quick to assume that a defective stump is evidence of the carelessness or incompetence of the surgeon who performed the amputation. A lad, 11 years of age, was brought to me for examination whose leg had been amputated four years before for a crushing injury, made by the wheel of a street car. The stump was in very bad shape, nothing covering the projecting end of the femur for two inches but thin and ill nourished skin; the cicatrix at the end of the bone had ulcerated. The stump was the seat of constant neuralgic pains, spasms, and was exceedingly sensitive to changes in temperature and the slightest mechanical irritation. My opinion was that a reamputation would be necessary, preferably through the shaft of the bone above the epiphyseal cartilage to prevent the recurrence of a bad stump. The injury was the subject of a suit of law, and the attorney for the plaintiff was anxious to show the painful and bad condition of the stump and the risk of reamputation as an additional element in damages. The amputation had been made by the railroad surgeon, and in the opinion of the family was improperly done. I was able to assure them that the bad stump was probably due to natural causes, for which the surgeon was in no way responsible, and that they were as clearly entitled to recover for a bad result from natural causes growing out of the injury as they would be if negligence were alleged.

A subsequent conversation with the surgeon showed that the limb was practically amputated at the knee by the injury, and that he simply severed some of the soft parts, shaped the flaps and dissected out the patella; he was deterred from making a section of the femur because of the collapsed condition of the patient and the fear that additional interference would result fatally.

The case is one of interest because of its bearings in malpractice suits and its general relations to amputations. It also emphasizes the fact that in the thigh amputations of children the section should be made above the epiphyseal cartilage, otherwise a bad stump inevitably results.

This is a type of a number of cases seen in which bad results have followed disarticulation at the knee in children. So far as the forensic aspects are concerned, the section ought always to be made above the epiphyseal cartilage. Another possible relation which has not been referred to, and which may have its forensic importance, is the amputation of legs that are paralyzed. I refer now to those flail-like legs that result from injury to the anterior horns of the spinal cord, in which there is complete motor paralysis of the legs, with atrophy of the muscles and of the bones, and failure of growth. Such limbs dangle about; their nutrition is low; they are exceedingly liable to injury because of inability to control them, and in many instances the patients themselves request amputation, or it is suggested by the physician in charge. I do not think with our present knowledge that these amputations are justifiable, particularly if there is sufficient power in the muscles which unite the pelvis to the thigh, the gluteal and psoas, to balance the leg upon the thigh. In these cases a resection of the joint should be made instead of an amputation, making the leg one piece from the hip to the foot.

SELECTIONS.

A Coroner's Perquisite.—The London *Lancet*, October 2, points out the absurdity of one of the fictions upon which the profits of coroners depend in England. In some parts of our own country a like superstition survives. "A very old and very persistent superstition has again dictated the action, or rather the inaction, displayed by the persons who first discover the body of a recent suicide. A poor fellow, named Henry Scott, recently committed suicide in a Suffolk village by hanging himself to a tree. It was stated at the inquest that an hour before he was cut down a man saw him suspended from a branch, but that instead of ascertaining whether life was extinct he went for the police, being under the impression that a body must not be touched save in the presence of the police. Some children also saw the unfortunate man and ran to tell their elders. But their elders did nothing, being under the

same curious impression. It can not be too widely known that the prejudice against touching a body save in the presence of the police is founded upon nonsense, and nonsense to which before now lives may have been sacrificed. The fault probably lies at the door of the police who, in cases where a body has been moved and a verdict has been subsequently returned against some persons unknown, have been known to hint that if things had not been disturbed they could have obtained a clue, the sort of clue, we suppose, the absence of which accounts for the unsuccessful inquiries into the death of Miss Camp. The duty of a person who finds a body is first to ascertain that it is a body and that of a fellow creature. If life remains a medical man should be sent for and afterward the police. If it is necessary to remove the body to ascertain that it is a body (this would always be the case when dealing with death by hanging) it will be well to take accurate notes of the position in which it was found for the information of justice." We may learn from the above and other observations by our candid medicolegal experts that, barring necessary expense, the normal rate of income of an ordinary or inexperienced or political coroner should not exceed \$2,000. This rule will properly apply to localities where violent deaths are comparatively rare, namely, in our less populous localities. In more crowded situations a more liberal tariff must have sway. As a general rule, \$5,000 per year is believed to be about all that a conscientious coroner may expect to claim after his legitimate expenses have been paid. Some coroners of cities of the larger size are said to be in the receipt of over \$15,000 per annum, and yet find that amount insufficient to meet the total expense account, but some of this outgo must be regarded as intercurrent, non-legitimate or possibly political in its nature. One thing is very certain with regard to politicians who get elected to coronatorial berths, however large their revenues may be, they find it difficult to "lay up a cent."

Soil Bacteriology and Water-Supplies.—Mr. Hunter, a Scottish analyst, in the *Sanitary Journal*, repudiates the idea that the day of chemistry has passed in the sanitation of our water-supplies. He likewise repudiates the assertion that chemistry and bacteriology tend to produce contradictory and confusing results. He says: "The production of carbonic acid in fertile soils is part of the life work of those important soil organisms with which every fertile soil is teeming, and the removal of this carbonic acid is the principal function of the field drain. In sterilized soil there is practically no solvent action results from dain with its .02 per cent. of carbonic acid in solution. Moreover, we many years ago proved that groups of our soil organisms possessed the power of decomposing stable double silicates, and we are therefore compelled to conclude that the salts dissolved in the river, well and drain water were due purely to the wondrous works of those living micro-bodies in the soil, and certainly not to purely chemic interchanges such as are, with such simplicity and accuracy, painted in books. From what has been said, you will have gathered that the composition of waters is very largely due to life in the soil; and it follows that the composition of waters may be materially altered by: 1, inoculation of soils or gathering ground with advantageous organisms, if necessary; and 2, by altering the compositions of the soil, so that the multiplication and working of those advantageous organisms may be encouraged.

"In recent years some medical officers, who have not yet learned the rudiments of bacteriology, have not hesitated to say that the chemic examination of waters is positively useless, and nothing but a biologic examination will satisfy them. I am quite as alive to the value of a biologic examination of water as any medical officer in Scotland can be, but I can only understand their criticisms by realizing that some of them have got hold of a word they do not understand, *bacteriology*, and that they are ringing the changes upon the public and their employ-

ers, the County Councils. It is now many years since, in conjunction with my worthy and able friend, Dr. T. G. Nasmyth, undertaking the bacteriologic part; and it is simply a fact that, we arranged to independently examine waters biologically and chemically. Dr. Nasmyth in every case, there was no single exception, the two methods agreed. More recently, Professor Bowhill of San Francisco, who is probably one of the very best practical bacteriologists of the present day, whose recent contribution to the bacteriology of water is the most masterly piece of work in this department that has ever been done, has had a similar experience. He has exchanged many samples with the State chemist, and in every case, good or bad, the biologic results have absolutely confirmed the chemic. These critics suggest that it is possible for a water to be bacteriologically bad, and that the badness will not be revealed by purely chemic analysis; but what they suggest is most impractical and well-nigh impossible of happening, unless some skilled bacteriologist were to grow pure cultures, say of typhoid bacillus, and introduce those into a water-supply, minus the medium in which they were grown. That, I take, however, to be impossible; but even were it not so, the presence of typhoid bacilli in such a case would be by intention, and the work of a demon. If the chemic examination of waters is worthless, it is more than time we had a new public health act, because at the present moment, as the law stands, if any question arises as to the quality of a water 'it shall be submitted to the official analyst for chemic examination;' not to the analyst or the medical officer of health for bacteriologic examination, but to the chemist for chemic examination. What, then, I maintain is that while we do not, and dare not, overlook the importance of the biologic examination of waters, the wholesale condemnation of the chemic examination is, to say the least of it, rash, and is attempted only by men who, in my opinion, are absolutely incompetent to judge either of the one method or the other."

Innominate Aneurysm Treated by Electrolysis; Recovery, Subsequent Necropsy.—In the *British Medical Journal*, Dr. Stewart of Philadelphia reports an important autopsy made on a recovered case of innominate aneurysm treated by the introduction of gold wire and by electrolysis. The autopsy took place about three and one-half years after a complete cure of a very large aneurysm. Ten feet of snarled, coiled fine gold wire were used in the case. The case was unfortunate in that the man was an alcoholic and syphilitic, and the subject of pronounced aortic and mitral disease, with extensive cardiac enlargement, generalized endarteritis and chronic nephritis. The aneurysm formed a large and prominent swelling at the roof of the neck. It was regarded as springing from and being limited to the innominate artery. The sac wall was of extreme thinness and, at least externally, was unprotected by clot. This, which was apparent to the eye and touch, was further demonstrated by puncture with needles. At the time of operation the sac wall seemed on the point of bursting externally in several situations over which the skin was extremely thin and bluish. The result of electrolysis through the introduced wire was very decided. Clot formation, leading apparently to solidification of the sac, was early manifest. The patient lived for nearly three years and a half after the operation, and finally died as the result of the formation of a large thrombus in the middle cerebral artery, the result of the advanced endarteritis present. Despite the most unfavorable condition of the patient, his bad cardiac and renal disease and generalized arterial sclerosis, his having had syphilis and being a steady drinker of spirits, the result obtained speaks strikingly in favor of this procedure as a method of treating sacculated aneurysm. The sac was found to be of extreme hardness, with complete consolidation and obliteration of its cavity. At the autopsy, which was performed four hours after death, the heart was found to be dilated and hypertrophied, the aortic and mitral valves sclerosed and insufficient, and there was a

distinct fusiform aneurysm at the junction of the transverse and descending portions of the aorta, which throughout was the seat of extensive atheromatous degeneration. The sacculated aneurysm springs directly from the root of the innominate artery. The aneurysmal sac is approximately the size of a fetal head at term, length thirteen centimeters, transverse diameter nine centimeters. The sac is completely consolidated with organized coagula, in which lie the coils of wire. The consolidated sac has at its base a small cul-de-sac, the remains of the innominate artery. This, from the aorta, admits the little finger to a distance of four centimeters through the annular ring, sharply defined, two centimeters in diameter. The cul-de-sac was noted to contain in its interior a small coagulum, presumably of postmortem formation. The sac itself was very firm and wholly solidified, and when cut into was found to be completely occupied by organized material, in the interstices of which lay the coils of fine gold wire. Brain: A large thrombus is evident in the left middle cerebral artery. Softening has occurred in the region of the corpus callosum, caudate and lenticular nucleus and in the internal capsule of the left side. This cerebral thrombosis was evidently the cause of death. He has now treated two cases of sacculated aneurysm by the employment of electrolysis through introduced wire, and has directed the technique in a third successful case. This has naturally led him to give a good deal of attention to the subject. The result in his second successful case, the necropsy of which is here reported, and that obtained in the case treated by Dr. Hershey of Colorado, in which the solidification of the aneurysm resulted by this method, is sufficiently suggestive to engage the attention of the therapist. The method of treating aneurysm by the introduction of wire was first introduced by Moore at the Middlesex Hospital, in 1864. His case died of sepsis. Stewart thinks that in this case a great excess of wire was introduced. The cases of Loreta and Moore (both abdominal aneurysms), in which six feet and four to five feet of wire were respectively introduced, both resulted in cure. Stewart employs under strict antiseptic precautions fine silver or gold coiled wire, which, after the introduction of a moderate amount, will assume snarled spiral coils which will reach the whole caliber of the sac. Failures have occurred through the use of wire which was too stiff or too bulky; and steel or iron wire will decompose and fill the sac with a granular detritus which may be the cause of emboli. Galvanism with a rather strong current, 40 to 80 milliamperes, Stewart considers a very important part of the treatment, for, although the presence of the wire itself may be sufficient to obstruct the blood stream sufficiently to cause thrombosis, the passage of the galvanic current through the cells is observed to cause much more rapid and firm solidification.

Perforating Ulcer of the Foot; Operation; Recovery.—Dr. Cazenavette, in the *New Orleans Medical and Surgical Journal*, November, reports a case of the above named affection as follows:

On July 17, 1896, S. W., a negro 29 years old, was admitted to Ward 1, Charity Hospital; formerly brakeman of freight trains, now barber; single; good ancestral and personal histories. In 1888 he received a gunshot wound in the back. A 38 caliber ball entered on a level with the eleventh rib, one and one-half inches from the median line. He fell, and on attempting to rise realized that he had completely lost control of the lower limbs. The next day he was taken to the hospital. Complete paraplegia of the lower extremities was marked; paralysis of the bladder necessitating catheterization soon became apparent. Acute symptoms of cystitis were early manifested. The patient suffered agony for a week and had high fever. The penis became very much inflamed, edematous, the meatus everted and a membranous structure was extruded. This was secured, extracted and found to be a complete membranous cast of the bladder, with the opening that of the urethra. A

few months later the patient left the hospital, slight paralysis of the right leg remaining.

In 1892, four years after his spinal injury, while working on a freight train, fearing a collision, he jumped to the ground and pierced his right heel with a spike; according to his statement it entered fully an inch. A few days afterward he applied for treatment at the out-clinic of the Charity Hospital. Irregularity of attendance and neglect resulted in a local ulcer. The inconvenience of this ulcer rather than pain decided him to abandon his occupation and go to the hospital. Just after his admission he was smitten with the smallpox and sent to the pest house, where he finally recovered. As only the history of traumatism was given the ulcer was treated as a simple traumatic one. Thorough antiseptics and asepsis, with rest, were the features of the treatment. The ulcer did not improve. It increased in depth rather than in surface. This argued that the true cause had not been determined, for such an ulcer, due solely to bacterial contamination (no diathesis nor dyscrasia present) treated as it had been with antiseptic care and rest in the recumbent position, would have healed in a short space of time. The ulcer of five years standing was situated on the right plantar surface, its posterior margin being about an inch from the end of the heel. It was irregular, circular and about an inch and a half in diameter. Its surface was sunken beneath its borders which, thickened and indurated, overhung the surface of the ulcer, causing it to appear smaller than it was in reality; callosity was a prominent feature. As previously stated, insensibility was marked all over the plantar surface of the foot. The diagnosis of trophic ulcer was made.

Dr. Matas, surgeon in charge, decided to try total extirpation with the view of reaching healthy tissue, to be immediately covered with Wolfe's grafts. The area of operation was duly prepared.

On January 15, two months after the operation, there remained two uncovered areas of granulations, each scarcely exceeding a quarter of an inch in diameter. On January 27, it was thought advisable to cover these granulating surfaces with grafts like the preceding, after the same preliminaries. On account of the impairment of sensation on the right thigh, the grafts were again taken from the left. The surfaces to be grafted after denudation were triangular in shape, with their apices in the center of the old ulcer, extending to the bone, and measured about five-eighths of an inch at the bases. Six days later the wound was dressed. The epidermis on one graft had begun to peel and both grafts were adherent. At the following dressing the epidermis on the other graft had peeled off and the whole seemed to be doing well.

At my last visit to the patient, on February 20, three weeks after the second operation, the healing process had progressed uninterruptedly, with the exception of the apex of one graft, upon which there appeared a granulating surface not exceeding a quarter of an inch in diameter. As those granulations and the surrounding tissues are healthy we are justified in assuming that this small area will reach the stage of epidermization without obstacle.

Perforating ulcers have been looked upon by the profession at large as almost incurable. When they are due to a progressive trophic lesion of the spinal cord their cure is apparently beyond our reach, but when caused by a non-progressive lesion, as we have in this case, the surgeon should supply general surgical principles which serve in the treatment of other rebellious forms of ulceration, viz., a total and complete extirpation of the diseased area, including the osseous as well as the soft parts; this is a matter of fundamental importance; the substitution of the excised part by large cutaneous grafts involving the whole thickness of the skin, as suggested by Wolfe and amplified by Krause, by which the denuded surface is immediately protected and the weakened part reinforced by the addition of new and vigorous material, endowed with all the attributes of living and resisting protoplasm.

The Father of English Surgery.—John Ardene, a contemporary of Chaucer, Wycliffe, Froissart, Petrarch and Guy de Chauliac, belongs to a period of extreme interest in the evolution of general and surgical literature, and it will be seen that he within his sphere gave no mean aid toward the advance of a higher culture. Of biographic facts we have but little to record, but it is known that he was born in 1307 and practiced at Newark in Nottingham from 1349, the year of the plague, until 1370, when, at the age of 63 years, he settled in London. Thenceforth he appears to have devoted his days to the publication of his experiences, in the form of treatises upon medicine and surgery. It is surmised that he had been previously attached for a time to the English forces during the French wars in the capacity of field surgeon, for there is no doubt that he was well acquainted with France and its language, and that he had an extensive experience in the treatment of wounds; but although he calls himself *chirurgus inter medicos* there is nothing to show that he had possessed a Master's degree or any formal license for the exercise of his calling. However, this may be, his writings prove that he was a man of clerical attainments, with a good knowledge of Latin and French, and well-read in the available literature of his profession, quoting freely from the works of the medieval surgeons, the Arabs, and even from the Greeks. That he achieved fame as a surgeon is no less certain. He refers with pardonable pride to a number of distinguished patients whom his ministrations had restored to health, and he is said to have received from the Black Prince, a grant of land in Connaught, and with it the right to prefix the noble particle "de" to his name. It is hard to say whether the position of an Irish landlord was more enviable then than now, but the colossal fees he was able to command from his wealthy clients probably rendered him independent of his Hibernian rentals. In his case, as in that of Guy de Chauliac, the literary labors which have preserved his memory were the outcome, and not the cause of his success, for it was not until he had won an honorable repose that he found leisure to give the world the secrets of his practice. His writings, couched in fair Latin and dealing with nearly the whole of medicine and surgery as they were then known, were noteworthy productions of a reactionary but still illiterate age, and they appear to have been duly valued during the next three centuries, although none received the honors of the press except an abstract translation of an essay on fistula, which was printed in 1588 by John Read, as an appendix to a translation of Francis Arceus on wounds. When Ardene was in his prime there was but one scientific center in Europe where any pretense of surgical teaching was maintained. The once famous school of Salerno had already become effete. The Italian revival under William of Saliceto, Theodoric, Lanfrank, Modini and others, had given place to the old stagnation against which Bologna had made a valiant fight before sinking into premature decay. Paris, too, after listening to the teaching of Lanfrank and of Henri de Mondeville, had absolutely turned her face to the wall, and Montpellier alone, thanks in part to its geographic position, which brought it within nearer touch of Arab learning, was liberal enough to sanction the cultivation of anatomic and surgical science, not, indeed, within the walls of its university, but in extramural classes, in which, among others, Guy de Chauliac, the greatest surgical figure of the age, took a leading part. Even this tolerance soon died out, and Montpellier went the way of Salerno, Bologna and Paris, but not until the work of Guy de Chauliac and John Ardene was ended. In England the age of Chaucer and Wycliffe made no provision whatever for medical progress, and there was no school of anatomy or surgery throughout the land, and no English contributors to the literature of the subjects could be said to exist, if we except such theoretic references as may be found in the works of Gilbertus Anglicanus and John of Gaddesden, written, like all medical treatises of the time, in Latin. It is true that

the writings of the Arab physicians, which gave an imperfect sketch of Greek surgery, and those of William of Saliceto, Roger, Theodoric, the Four Masters, Lanfrank, de Mondeville and, after 1363, the masterpiece of compilation, the *Chirurgia Magna* of Guy de Chauliac, were also procurable in Latin guise, but the knowledge to profit by them was rare indeed in the ranks from which the representatives of English surgery were drawn. In the fourteenth century the lot of those of our countrymen who fell in need of our surgical ministrations was a sadly precarious one. The art was regarded by the educated physicians then, and for centuries later, as beneath their dignity. As expressed by our Elizabethan surgeon, John Read, in the doggerel which he and his fellows loved to prefix and append to their professional writings:

"Chirurgery moreover is
Abhorred of the Phisition,
Who doth esteeme it as a thing
To vile for his profession."

His writings convey a vivid picture of the man. It is easy to see him as the leech of courtly and obliging manners, sober in attire, and moderate in speech, and endowed with a self-restraint born of self-respect, with a tact that bore him well through the many difficulties that must have beset the thorny path of the *chirurgus* in his day, and with a strong common sense that never rose too near the dangerous level of genius; a goodly man and true, kindly and honest, but shrewd withal, with a quick eye to the main chance and a capacity for raising expediency to the dignity of principle. He was through all a surgeon, a scholar and a gentleman, and in the records he bequeathed he stands before us as one whom we, his professional descendants, may accept with pride and veneration as the Father of English Surgery.—London *Lancet*.

First Complete Excision of the Stomach in a Human Being.—Dr. Carl Schlatter, in the *Medical Record* of Dec. 25, 1897, describes the case as follows: The personal observation forming the subject of this paper, relates to a woman 56 years old. In her case I completely excised the stomach, even beyond its cardiac extremity, and then restored the continuity of the alimentary canal by stitching a loop of small intestine into the lower end of the esophagus, *i. e.*, esophago-enterostomy. I first saw the patient at the surgical polyclinic on Aug. 26, 1897. An inspection of the abdomen revealed a marked bulging between the left hypochondriac region and the umbilicus. The abdominal parietes were flabby, and palpation easily revealed an oval mass of hard consistency in the region of the stomach. The tumor was freely movable. Its size was about that of two fists. Very marked emaciation was found. The patient was unable to retain any kind of nourishment. She clamored for relief by surgical interference. She was admitted to my wards for further careful observation. I did not feel confident that gastrectomy, or even gastro-enterostomy, could be successfully performed, on account of the large size of the tumor. The patient continued to reject almost everything, including fluids. The iodid reaction of her saliva (after exhibition of iodid of potassium) required forty-seven minutes for its first appearance. The chemic examination of her gastric secretion showed no trace of free hydrochloric acid. . . . On Sept. 6, 1897, acting for Professor Krönlein, I performed laparotomy under morphin-ether anesthesia, and with strict antisepsis, incision in the median line, extending from the ensiform process to the umbilicus. As I had anticipated, the entire stomach presented itself in the shape of a hard mass extending from the cardiac to the pyloric extremity. Strangely enough, the tumor was freely movable. It was readily lifted out of the peritoneal cavity. Three rather soft lymph nodes were found at the greater curvature near the pylorus. The stomach being diseased *in toto*, a gastro-enterostomy was impossible. I at once decided to attempt to excise the entire organ, or take recourse in a jejunostomy. I first freed the stomach

from all its attachments at the greater and lesser curvature, having previously shut off the general cavity of the peritoneum by sterilized compresses. The omentum was incised between Péan's forceps. Silk sutures were used. The stomach was then forcibly dragged downward so as to enable me to reach the esophagus. The left lobe of the liver had to be constantly held upward by an assistant, in order to permit me freely to manipulate within the field of operation. In this way I finally succeeded in securing the esophagus rather high up, by means of a Wölfler clamp. A Stillé forceps was next fastened closely to the cardiac end of the tumor. Then the stomach was severed directly beneath the esophageal extremity. As the esophageal incision appeared somewhat oblique, I proceeded to place a small occluding suture at the gastric wound. The same steps were now repeated at the pyloric end of the stomach. I next mobilized the duodenum as far as possible toward the head of the pancreas. Then having applied a duodenal compressor, and likewise a tumor clamp, I removed the entire stomach between the two points of compression. I also dissected out the lymphatic nodes above mentioned. The patent lumen of the duodenum was treated, like the esophageal opening, with iodoform gauze. The broad bridge joining together different divisions of the alimentary canal had now been entirely removed. I next tried to pull the duodenal opening upward toward the esophageal cleft. It was only with considerable difficulty that the two could be made to touch. It was manifestly impossible to join them by direct suture. I therefore invaginated the duodenal rim and closed the opening by a double suture. I then searched for a suitable coil of small intestine. Beginning at the duodeno-jejunal fold, I followed down the intestine for about fifteen inches. The presenting knuckle of intestine I grasped, and pulling it over the transverse colon, I placed it against the esophageal slit. A piece of this intestine, about five inches in length, was secured between two Wölfler clamps. By means of sutures not going deeper than the serous coat, the intestine was then attached to the esophageal stump. A longitudinal slit about one inch in length was then made into the bowel. Then the mucous membrane of the esophageal end was firmly united with the intestinal mucous membrane by a continuous circular suture. The material employed was silk. Above this a second suture, extending through the muscular and serous coats, was introduced. A Lembert suture finally completed the stitching, which now seemed to hold. The esophageal and duodenal clamps were then removed, the former having remained in position for over two hours. On dropping back the organs into the abdominal cavity, the sutured portions showed marked retraction upward toward the esophageal part of the diaphragm. The abdominal wound was closed in the ordinary way by silk ligatures. Less than eight ounces of ether had been employed during the narcosis, which had fortunately been a very quiet one. Pulse after the operation 96 a minute, steady and of fair volume. There had been a very slight loss of blood during the course of the operation, which, however, had lasted nearly two hours and a half. There was a steadily progressive increase in the weight of the patient after removal of the cancerous stomach.

There being no food receptacle after ablation of the stomach, it became obligatory to feed my patient at first with minute quantities of food, given at short intervals. The results of this method of procedure were in all respects happy ones. Quantities of food approaching ten ounces seemed to excite vomiting. So, too, cold fluids resulted in diarrheal discharges, and may have been partly responsible for the rise in temperature, observed for some little time after the operation. Keeping in mind the absence of mechanical function, the patient's dietary was at first a strictly fluid one. But as early as the second week after removal of the stomach, semi solid and even solid food was allowed. It was retained and digested without discomfort. The patient having only a single tooth, mastication was of course quite imperfect, otherwise it seems to me possible that an ordinary mixed diet might have succeeded at a still earlier date. Some weeks after the operation the patient's ordinary daily dietary was as follows: At regular intervals of from two to three hours she took milk, eggs, thin gruel or pap, tea, meat, rolls, butter and Malaga wine. The daily quantity amounted to one quart of milk, two eggs, two to three ounces of pap or gruel, seven ounces of meat, seven ounces of oatmeal or barley water (as thick almost as gruel), one cup of tea, two rolls and half an ounce of butter. Personally I felt most con-

cerned about the obliteration of all chemic activity on the part of the absent stomach. I soon perceived that adding pepsin and hydrochloric acid to the food was theoretically as inadmissible as it had been found practically valueless. The alkaline fluids of the intestine at once neutralized the acid and rendered the pepsin inert. Fortunately it soon became apparent that despite the absence of acid pepsin, proteins were readily assimilated in the intestinal tract. . . . Products of abnormal intestinal fermentation or decomposition (skatoxyl and indoxyl) were either not at all found, or else discovered only in traces. . . . The patient objected to swallowing charcoal. Huckleberries were at three different times found in the passages, twenty-four hours after having been swallowed. Apart from a daily recurring diminution in the quantity of excreted chloride, the urine of this woman has remained normal since ablation of her stomach. The daily excretion of chlorid of sodium has been found to vary between the limits of 0.6 per cent. and 0.95 per cent. It should be stated in this connection, however, that, complying with the wish of the patient, her food is prepared with less salt than that of the other ward patients. The stools were well formed, of normal consistency, and light yellow in color. The microscope showed large numbers of fat globules and fatty crystals, some undigested vegetable fibers, but no undigested animal fibers or connective tissue. Large quantities of triple phosphates were observed. The number of micro-organisms was normal. Altogether repeated examinations revealed no noteworthy departure from a condition of perfect health. No matter what theoretic physiologic notions we may have imbibed from lectures and textbooks, the woman under observation had repeated attacks of ordinary nausea, retching and vomiting. We must needs conclude, therefore, that the rôle of the stomach (*i. e.*, its anti-peristaltic efficacy) in this direction has been very much overrated. While the vomited substances showed an acid reaction, this was not due to the presence of free hydrochloric acid. In view of the fact that the patient ejected as much as thirty ounces at one time, it seems reasonable to suppose that the remaining portion of the duodenum may have already begun to show distention sufficient to produce a sort of compensatory receptacle for food, perhaps nature's attempt in the direction of the new formation of a stomach. In endeavoring to explain vomiting without a stomach, we should remember that the act itself is far from being a simple process. It is due to nervous action on a complex motor apparatus, consisting of pharynx, esophagus, stomach, diaphragm, and abdominal muscles. It is not surprising, therefore, to have witnessed in this woman an ordinary attack of bilious vomiting, superinduced by a mere psychic disturbance.—*Abstract.*

How the Surgeon Lost His Fee.—A famous Vienna surgeon was asked, by telegraph, how much he would charge for a capital operation on Reb Chaim Rosenbaum, a young, promising merchant in darkest Polish Russia. The reply was that 5,000 gulden (\$2,000) would be a fair compensation for the job. After various negotiations it was agreed that the desired amount should be paid after the operation was performed. The surgeon left sunny Vienna at once to emerge, after a thirty-six hours' journey, in the garlicky atmosphere of a small Polish town. There he was met by a congregation of long-bearded and long-coated individuals with long faces, who explained that the life-saving professor was too late this time and that good Reb Chaim Rosenbaum was gathered to his fathers the previous night. The surgeon's disappointment was so much greater as the mourning survivors did not show any willingness to pay his expenses. He concluded, however, to take a day off in the town. The population heard of the presence of the celebrated surgeon and it was not long before he saw himself surrounded by a crowd of surgical cases. He was kept busy operating the whole day, receiving fees of 50 to 100 gulden from each patient, so that, while not getting the stipulated 5,000, his trip was not a dead loss. When on the following day he was entering his train to return to Vienna an old Polish gentleman most politely approached the professor, wishing him a lot of good things, praising his skill and many virtues, and finally saying that the whole town was forever under deep obligation to him, and to show his everlasting gratitude he would confide a secret to him. The professor could do no better than to listen and great was his surprise when he heard the following confession: "Don't you know,

dear professor, that there is some mistake about Reb Chaim Rosenbaum's premature end and that in fact he found it preferable to stay with us instead of being gathered to his fathers. Among the many patients you operated upon yesterday you also operated upon Reb Chaim Rosenbaum, and God bless you, you were satisfied to take 50 gulden instead of 5,000. Thanks to Heaven and to the greatest of the great professors, he is on the road to recovery. Great is your kindness and great is Allah!" The professor made an unsuccessful effort to smile, the locomotive began to puff, and when next he goes to Rosenbaum's town, without a payment in advance, may we be there to see.—*Clinical Recorder*.

PRACTICAL NOTES.

Combination of Iodid and Thyroid Treatment of congestion of the thyroid gland. Halipré advises combining these two treatments as indicated in acute cases of congestion and hypertrophy. He reports a case cured by the combination, rebellious to either alone.—*Semaine Méd.*, December 22.

Can Liquids Injected into the Gums Find Their Way into the Bones?—Dzierzawski replies in the affirmative as he found that a solution of methylen blue injected into the interdental papillae found its way into the upper jawbone as far as the antrum of Highmore. The lower jaw was only colored by it in the close neighborhood of the injection.—*Chl. f. Chir.*, November 13.

Purulent Peritonitis in Pregnancy.—Fabricius reports a case operated on, releasing a large quantity of fetid pus, but the uncontrollable vomiting that followed made abortion necessary. The patient recovered rapidly. When laparotomy was performed the diagnosis was still uncertain, but temporizing would have proved certainly fatal.—*Gaz. d. Osp. e d. Clin.*, December 9.

Gelatin Vaginal Tampons.—J. Fischer presented some convenient tampons at a recent meeting of the Vienna Medical Club. The cotton impregnated with the desired substance is inserted in a gelatin shell provided with a cover opening inward. The patient can easily introduce the shell herself. The gelatin melts in twenty minutes, and the cotton wad is removed the next day by means of a string attached to it.—*Therap. Woch.*, December 5.

Revelsion and Infective Processes.—V. Martini reports the results of an extensive series of experiments to determine the effect of revulsive medication on the infective processes beneath. He states that they are absolutely ineffectual; the subjacent infective process and the superficial pursue their respective course without the slightest reciprocal effect. Useless in all, they may prove distinctly injurious in some cases.—*Gaz. d. Osp. e d. Clin.*, December 9.

Decomposition of the Blood by Chloroform.—Desgrès and Nicloux state that chloroform in contact with potassium or any alkaline disengages oxid of carbon. Experimental investigation showed that the alkaline blood affected inhaled chloroform in the same way, one subject having 1 to 1000 of oxid of carbon to 5 kilograms of blood, total weight 65 kilograms. While this proportion is not very large, still it may explain some of the accidents due to chloroform.—*Presse Méd.*, December 11.

Therapeutic Ferments; Beer Yeast in Diabetes.—The diet can be varied in diabetes if two or three tablespoonfuls of beer yeast are taken during the day at meals, disguised in beer or white wine. It promotes assimilation and destroys the sugar derived from the food, while preventing the accidents that follow an exclusive meat diet. It is especially useful in cases in which the sugar is chiefly derived from the food, but is beneficial in all. It should be discontinued for a few days from time to time, or less taken every three or four days.—*Gaz. Méd. de Liège*, December 23.

Treatment of Pott's Disease with Sublimate.—Capparoni has succeeded in gradually improving and curing the paralysis and pain in three cases of Pott's disease, two cervical and one dorsal, by a daily subcutaneous injection of 10 centigrams of sublimate. None were syphilitic. In two months the first case was able to walk. She returned to the hospital two years later with paralysis of the members: a second course soon restored her. She had borne two children in the interval.—*Semaine Méd.*, December 22.

Substitution of Sea Water for Saline Solution in Hypodermic Injections.—Hallion recommends diluted sea water for this purpose, as it is better supported and can be administered in larger amounts and much more rapidly. It is infinitely less toxic than the solutions of sea salt usually injected. Another point is that sea water lowers the temperature while salt solution raises it. The density of the urine is less with the former, indicating better functions of the kidney.—*Semaine Méd.*, December 8.

Prevention of Pitting in Variola.—Satisfactory results are reported by several practitioners with Finsen's method of keeping the patient the entire period of the disease in a room illuminated only with red light, like a photographer's dark chamber (*Presse Méd.*, December 22). Kolbassenko recommends the following salve for dressing the eruptions: Ichthyol, 19 grams; almond oil, 60 grams; lanolin, 20 grams. Apply externally three times a day until the scabs fall.—*Gaz. Méd. de Liège*, December 23.

Orthoform in Hypodermic Injections for Surgical Anesthesia.—Hirschbruch states that orthoform will produce a lasting local anesthesia sufficient for minor surgery, while the non-toxicity is a great advantage. He first injects into the skin a small amount of a 2 per cent. solution of cocain (about 2 milligrams of the salt) and then injects in this spot in several points 1 c.c. of distilled water containing 3 per cent. orthoform in solution, shaking the syringes well at each injection, as the orthoform does not dissolve but is merely held in suspension.—*Semaine Méd.*, December 22.

Anti-Diphtheria Serum in Asthma.—Proceeding from the fact that anti-diphtheria serum causes the pseudomembrane to be thrown off by means of an exomosis from within outward. Professor Revilliod of Geneva, has tried it in several severe cases of asthma, which he has cured after they had resisted all other remedies for years. Improvement was noticeable after the first injection in the first case, increasing with each one until the recovery was complete in five months with ten injections. The second case was cured in ten days with three injections. The third with six injections in two months.—*Therap. Woch.*, December 5.

Fluoroscopy of Picuritic Effusions.—Bergonié and Carrière report that the fluoroscope shows the displacement of the liquid as the patient assumes various positions, and with the motions of the diaphragm. Purulent effusions seem less opaque than the serous. But its principal value consists in the information derived in regard to the condition of the lungs above the effusion. It completes Grancher's schemas, reveals bacillary lesions and has a great prognostic value. In one case the clinical data were at fault owing to adhesions, which prevented the "sou" sound considered by Pitres pathognomonic.—*Semaine Méd.*, December 15.

Continuous Suture in Two Layers.—Mikhailoff obtains remarkable solidity with his suture described and illustrated in the *Presse Méd.* of December 8. It resembles the sewing machine stitch, which consists of a series of loops over a second thread. The thread is passed through the top of the wound. A loop on one end is drawn through the tissues, forming a double thread in them. Two loop stitches are taken in this way, when the ends are crossed and a second row of two loops applied, or the ends can be crossed between each stitch. The strength of the double thread inside the tissues and crossed threads out-

side, especially adapt this suture to wounds or autoplasmic operations in which there is a large loss of substance.

Severe Hemorrhage after Extirpation of Neoplasms Controlled by Cocain.—Grazzi removed a large pediculated papilloma from the larynx of a woman who shortly before passed through an attack of influenza. The patient was seized with violent coughing and blood-spitting, which the usual remedies failed to control. After two hours of vain attempts he finally swabbed the larynx with a 20 per cent. solution of cocain, which stopped both the coughing and the hemorrhage for a while. The cocain had to be applied three times before all hemorrhage ceased. He reports another case of the ablation of a simple polyp of the nose after an attack of influenza, likewise followed by excessive hemorrhage.—*Semaine Méd.*, December 22.

Electricity in Elephantiasis.—The conditions peculiar to early childhood render the action of electricity especially beneficial in lymphangitis, and Moncorvo reports "magnificent" results attained with the faradic and galvanic currents. Treated in the initial period of its development, the formation is arrested and in many instances subsides completely. In more advanced cases the morbid tissue is transformed more or less rapidly. Elastic compression and hydrotherapy were combined with the electricity. *O. Brazil Medico* of October 8 and 15, contain his communication in full, accompanied by several illustrations of remarkable manifestations of the disease in early childhood. One infant, well developed otherwise, looks as if his foot had been inserted in an enormous watermelon. In another, congenital, the disease assumed the fibrous and cystic form.

Naphthalan for Skin Therapy.—A series of observations has been made in Professor Finger's out-patient department, by Dr. Pezzoli, on a new preparation named naphthalan which appears to combine the therapeutic properties of tar with those of naphtha. It is a dark-brown unctuous substance with scarcely any smell and a melting point of about 70 degrees C. When used as an ointment it leaves no stain on the patient's linen, after it has been washed. It is very useful in various forms of eczema, sycosis and common psoriasis, as well as in parasitic affections, such as ringworm and scabies. It should be used with a certain degree of caution, as if rubbed in too energetically it is liable to produce some folliculitis of the same nature as tar acne. It was tried in forty-two cases of eczema and appeared to be of value in all stages, which renders it a very convenient preparation for general or out-patient practice. Excellent results were obtained in all the fifteen cases of impetigo contagiosa in which it was prescribed. In scabies three applications were found to be sufficient.

Alcohol Vapor Compresses.—E. Heus has revived the old practice of applying alcohol to wounds, studying the *modus operandi* and finding that the beneficial results are due to the vapors of the alcohol penetrating the tissue. He promotes this by applying the alcohol on a six to eight folded mull compress, dipped in 95 to 96 per cent. alcohol, squeezed till it no longer drips with moderate pressure. Over this a broad layer of dry surgical cotton, one or two fingers thick, is laid, and a soft airtight covering renders the whole impermeable. The first dressing is renewed in twelve hours; less frequently afterward. A thin layer of dry xeroform gauze is applied under the alcohol, on open ulcerating wounds. His communication to the Moscow Congress is published in the *Therap. Woch.* of November 28, with instances of the remarkably favorable results attained with the vapor compresses, especially in eczema, furunculosis, carbuncles, gonorrheal epididymitis, etc., and also in aborting phlegmons and mastitis. They were equally successful with infected wounds.

Abortive Treatment of Endometritis with the Vapors of Bromin.—Nitot remarks that the true prophylaxis of parenchymatous metritis and chronic salpingitis consists in curing recent endometritis while the inflammation is still superficial, with some substance that will penetrate to the remotest crevices in the uterus, and even into the tubes, extremely antiseptic, diffusible and endowed with anticatarrhal properties sufficient to modify without injuring the tissues. Bromin, which is soluble

in water and disengages dense vapors at the ordinary temperature, is endowed with all these properties. A bottle with a double current sound attached is filled with a saturated aqueous solution of bromin; air is forced into the bottle by a bulb entering the bottom. The results attained with this simple treatment have been extremely satisfactory, as the healing vapors reach every point of the surface with sufficient force, and none of the disadvantages of a liquid.—*Journ. de Méd. de Paris*, November 28.

The Subcutaneous Injection of Quinin.—As quinin does not dissolve readily in water (1 to 800 aq.), the discovery that antipyrin rendered it much more soluble led to the combination of the two for subcutaneous injections. Laveran's formula is: Quinin hydrochlor. ; 3.0; antipyrin, 2.0; aq. dest., 6.0. With this mixture Blum secured remarkably favorable results in a severe epidemic of malaria in Algiers. The strange fact that a neutral quinin salt in a 50 per cent. solution failed to produce the slightest pain, induced Professor Santesson of Stockholm to investigate whether a new chemic substance had not been formed out of the combination, which he found to be the case, and named the compound quinopyrin. It is much less toxic than quinin, and the pain of an injection is no more than from salt solution. Quinopyrin (quinin 0.5 to antipyrin 0.33), reduced the temperature of a non-febrile rabbit 1.5 to 2 degrees. An injection of quinin 1.0 with antipyrin 0.66 produced merely a slight intoxication, temperature and pulse scarcely affected. The same quantity administered per os produced marked quinin intoxication and lowered the temperature 1 degree.—*Deut. Med. Woch.*, No. 36.

Crossed Adductor Jerk.—In a recent number of the *Journal of Physiology*, Dr. Purves Stewart has a short paper dealing with this subject. The peculiarity of a crossed jerk is one which is not infrequently observed, and essentially consists in movement of the opposite leg when an attempt is made in the ordinary way to elicit the knee-jerk on one side. In Dr. Stewart's case, if the right patellar tendon was tapped, two jerks occurred, one of the right quadriceps extensor, the other of the left adductor muscles, and conversely of the right adductor muscles and the left quadriceps extensor when the left patellar tendon was tapped. The jerks of the two legs appeared to occur simultaneously, but an apparatus was devised to show: 1. The moment at which the patellar was tapped. 2. The moment at which the knee-jerk occurred. 3. The moment at which the crossed adductor jerk took place. The instrument is described in the paper, and three photographs are also reproduced of successful tracings taken during the experiments. These show clearly that the crossed adductor jerk occurs at an interval distinctly later than the knee-jerk, the average delay between the occurrence of the knee-jerk and the crossed adductor jerk in the three experiments being 0.057 of a second. This interval is considerably shorter than Dr. Glynn found in a case of crossed vastus internus jerk. Dr. Stewart mentions that different opinions have been held as to the nature of the crossed jerk, some observers considering that it is a true reflex, others that it is a direct muscular jerk produced by a sudden stretching of the adductor muscles resulting from the "jar" to the pelvis caused by the tap on the patellar tendon; others also hold that the adductor jerk is due to a sudden mechanical shock to the spinal cord. Dr. Stewart is induced, by a consideration of the results of his experiments, to conclude that the crossed adductor jerk is not the result of direct stretching of the adductor muscles by a shock communicated from the pelvis or due to a shock transmitted mechanically to the spinal cord, but is a true reflex occurring at a period distinctly later than the ordinary knee-jerk. The considerations which have chiefly led him to reject the two former views are that a tap on any of the bones near the knee, although equally likely to "jar" the pelvis, did not produce the jerk, and that only one adductor jerk was produced, and not one on the same side as well. He finds that the average time necessary for the appearance of the crossed adductor jerk is about 0.126 of a second from the time at which the opposite patellar tendon is tapped.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JANUARY 29, 1898.

SHENCK'S THEORY OF SEX DETERMINATION.

An eminent Vienna embryologist, now somewhat on in years, recently advanced what he considers strong evidence for a theory of sex determination in a communication to a Vienna medical society. This communication has not only been commended by Austrian and British medical journals, but has been widely and sensationally exploited in the lay press. Practically the position of Dr. SHENCK is that held by some obstetricians since the days when mother-right passed to father-right inaugurating the "couvade" by which after delivery the father must go to bed while the recently delivered wife arises to

"Serve rich possets to her husband in the straw."

SHENCK's theory of sex determination is essentially that of SHAKESPEARE's day advanced by Falstaff (HENRY IV, Act IV, Scene III) in answer to the reproaches of Prince John.

"I would you had but the wit: 'twere better than your dukedom. Good faith, this same young sober-blooded boy doth not love me; nor a man can not make him laugh; but that's no marvel, he drinks no wine. There's never any of these demure boys came to any proof; for thin drink doth so over-cool their blood, and making many fish-meals, that they fall into a kind of male green-sickness: and then when they marry they get wenches: they are generally fools and cowards."

This theory, which SHENCK claims to have demonstrated by the scientifically auspicious method of experiments on himself and wife without control experiments, is particularly an admixture of three older hypotheses: That paternal superiority determines the superior male sex. That paternal nutrition aids in determining this superiority, and finally that while the mother is of an inferior sex her good nutrition aids in determining the superior male offspring. All these theories more or less commingled have been ad-

vanced, as THOMSON and GEDDES have shown ("Evolution of Sex"), for centuries. They had a divine source according to MOYES, the paranoiac leader of the Oneida community. His claim (despite the large number of male hebephreniacs in insane hospitals among children of that community) was later supported by statistics ignoring these lunatics, collected (HOLBROOK's "Stirpiculture") by a Miss MCGEE of the community.

As most stress has been laid by SHENCK (like many preceding students of sex determination) on nutrition of the parents, the question arises does nutrition influence sex? If (as asserted by obstetricians biased by ante-embryology theories) sex be predetermined from the outset of ovum development, then this influence must at once be rejected. Hypotheses like these, advanced ere the days of VON BAER, must at once be tossed into the lumber-room of disproved theories. The modern position as regards the existence of sex in the ovum is that of LAULANIE, who has shown that in birds and mammals, three stages can be distinguished.

1. Germiparity, which is a return to that phase of lower cell development when reproduction was a function of all cells; a function which persists in the embryonic cancer cell to the destruction of the organism.
2. Hermaphroditism, where both sexes are evident.
3. Differentiated unisexuality.

BLAND SUTTON, PLOSS and others are of opinion from careful research that in individual development embryonic hermaphroditism prevails, but that one set of elements predominates over the other in the establishment of the normal unisexual state.

GEDDES and THOMSON point out that ("Evolution of Sex"):

The higher the organism is in evolution the earlier is its sexual fate determined. Only in the lower vertebrates (lamprey, lancelet, etc.), semivertebrates (sea-squint) and invertebrates, does prolonged neutrality of sex, or prolonged embryonic hermaphroditism usually occur.

There are then periods when nutrition may affect sex, strengthening the tendency from germiparity to embryonic hermaphroditism and from this to differentiated unisexuality. It is, however, evident that determination of the influence of nutrition on sex development in the higher vertebrates is difficult, since by HERBERT SPENCER's law of individuation unisexuality has early a preponderance.

As to the lower vertebrates DRUSING has (*Internl. Centralblt. f. die Harn. und Sex., Org. B. ii.*) shown that:

Sex is not inherited, but the result of various factors, acting not only at the time of impregnation, but at various times thereafter. Long after impregnation, when the embryo is already developed, nutrition is still influential, and may change the tendency even after the sexual organs have developed. Poor maternal nutrition may arrest female development and cause reversion to the male type.

The experiments of HENSON (which supplement and extend those of THURY) show that:

A very favorable condition of both ovum and sperm will lead to the formation of a female.

These results are however diametrically opposed to those of SHENCK and his numerous precursors since the days of ARISTOTLE. That both maternal and paternal nutrition have an effect is however demonstrable. Even that embittered doctrinaire opponent of the inheritance of acquired characters, WEISSMANN, admits that:

The origio of a variation is equally independent of selection and amphimixis, and is due to the constant occurrence of slight inequalities of nutrition in the germ-plasm.

That, however, the influence of maternal nutrition is most potent has been shown by repeated biologic experiments as well as in studies of degeneracy. The unimpregnated queen bee, or the unfed (with queen food) fertile worker bee as a rule, with rare exceptions, produce only drones. Feed the worker bee (which is an undeveloped female) like the queen and she becomes a queen capable of producing queen and worker bees on impregnation. The phthisic mother usually produces males. This fact was pointed out by that eminent American clinician DEWEES, nearly seven decades ago ("Practice of Physic," Vol. ii), and has been before and since observed in connection with tuberculosis and other factors producing degeneracy. If maternal nutrition be thus potent in producing females (a wealth of evidence in this direction is cited by THOMSON, GEDDES, MAUPAS, DRUSING and others), then not only is the Shenckian hypothesis unfounded, but an inferior result (the female) is obtained. The biologist, unbiased by oriental Semitic tendencies, like those of Dr. SHENCK anent the natural inferiority of woman, is naturally led to enquire whether the female from the standpoint of reproduction be really the inferior sex. SPITZKA, the leading American pupil of SHENCK, to whom the latter admits his indebtedness (SHENCK's "Embryologie," 1884), points out (*American Journal of Neurology and Psychiatry*, Vol. ii, p. 740) that:

The development of the female genital organs is a higher grade than that of the male. At the early periods of embryonic life there is but one development regarding sex, and that is male. It is at this period of life that causes operate either to retain the original development or to impress on such a further development into the female.

A casual glance at illustrations of the embryonic development of the reproductive organs in that popular text-book, GRAY's "Anatomy," sustains SPITZKA's position. The male organ remains unchanged from a type found in even invertebrates, while the female gains with increased complexity. Zoologists rank animals in evolution by female characteristics. The mammals are an excellent illustration of this principle. The inferior races of man differ less from the higher by their brain than by their pelvis. The female pelvis of the lower races, as HAVELOCK ELLIS has shown ("Man and Woman"), is masculine in type, while the male pelvis of the higher races is feminine. To a lesser degree (excluding hydrocephalic male skulls, like that of CUVIER) this is also true of the skull. The female of mammals has under her care for life,

that essential germ of the child, the ovum. The impregnated ovum for months is fed through her blood. She nurses the child for months after birth. Compared with this, the father's part in reproduction is slight. That the ovum is the essential germ of the child is shown by the existence of parthenogenesis (virgin generation). As SPITZKA remarks (*Medicine*, November, 1896):

The ovum possesses an inherent activity independently of fructification. How far this may extend in the direction of more mature development is shown by what is known as parthenogenesis, or virgin generation. This is the development of living beings without a father. Bees, some butterflies, ants and wasps notoriously multiply their kind without sexual congress. As a rule the parthenogenetic offspring are themselves incapable of further procreating their kind. But to this there are remarkable exceptions. The aphides multiply for many generations without the intervention of a male. Weigenbergh has shown that the silk-moth can be propagated as long as the male element is permitted to act at every fourth generation. The *Artemia salina*, a minute crustacean living in saline springs, reproduces its kind for years without a male being present, males being produced at definite intervals only (von Siebold). Among the vertebrata, parthenogenetic development has also been observed, though rarely reaching maturity. Thus, segmentation occurs in unfertilized ova of the chicken (Oellacher), of the fish (Burnett and Agassiz), and of frogs (Moquiu-Tanden). I have seen a blastoderm form in unfertilized ova of the toad fish (*Batrachus tau*). Henson isolated the oviducts of a rabbit, thus rendering the admission of semen impossible, while the ova, discharged at heat, were compelled to remain in these oviducts. Three years later he killed the animal and found that the ova had developed into twisted, club-shaped, hollow sacs. The development in the female ovary of dermoid cysts (containing bones recognizable as maxillaries with teeth, hair, and skin, rudimentary intestinal, glandular, and cerebral traces), even in undoubted virgins, proves that even the human ovum is capable of parthenogenetic development. While such development, so far as known to science, is always abortive, and while, as Washington Irving remarks, the ingenious maiden who today would attribute conception to any other cause than sexual congress would find it difficult to overcome the prejudice of scientists, yet embryology, while declaring immaculate generation improbable, does not pronounce it impossible. A worker bee is a highly organized creature with a well developed brain, wonderful sense organs, intricate muscular apparatus, yet it may be an offspring of an unimpregnated queen bee. What is a regular occurrence in one class of animals is sometimes observed as an exceptional one in another class. If the startling and apparently miraculous nature of a virgin generation of a living child be regarded as the sole objection to receiving such a fact, its defender might urge that the virgin generation of dermoid cyst with all the traces, however aborted, of vertebrate organization, is only a shade less startling and miraculous.

SHENCK has adduced no new evidence in favor of his old Aristotelian hypothesis. So far all the evidence at hand tends to show that while sex can be influenced by maternal nutrition and less directly by paternal, the female sex is most likely to be produced under favorable conditions. This is fortunate for man's future. Upon the perfection of the female, from a reproductive standpoint, turns future advance of the human race, since only through further development of the female pelvic organs and pelvis can the gains of the race be transmitted. Fortunately, enthusiastic oöphorectomists are rendering sterile no small number of female neurotics, thus lending potent assistance to the survival of the fittest pelvic organs. This beneficent result is not fully appreciated by those who decry such philanthropic labors. Discussion of the Shenckian hypothesis casts a decidedly optimistic light upon the labors of these painstaking gentlemen, since

imperfect female organs (the result of deficient maternal nutrition *à la bee*) are relieved from a task for which they were unfitted, to the benefit of the race, of the public charitable and correctional institutions, of the owner of the organs, and last, but not least, to the financial benefit of the enthusiastic oöphorectomist.

THE ABUSE OF SO-CALLED NERVE TONICS.

Many men and women in and out of the medical profession are resorting more and more to the employment of drugs which have, what has been falsely called, a tonic influence over the nervous system, since they find that the employment of such substances relieves them of symptoms arising from nervous exhaustion and enabled them to go on with their work for a time, in a manner which would otherwise be impossible. At one period the employment of nervous stimulants, other than tea, coffee and alcohol, was confined almost entirely to those of the medical profession who ignored the fact that drugs used for stimulant purposes produce ruin in the end.

Unfortunately for the laity of today a large number of semi-medical purveyors, finding the demand for their products not sufficiently great, have resorted to means by which they call the attention to the fact that remedies can be obtained which will be capable, in the language of a recent writer, of producing "a condition of veritable beatitude both mental and physical, so that the mind expresses itself in incoherent flights of the imagination." As a result of this a large number of individuals who have no reason to doubt the plausible advertisements which they read, resort to preparations of morphin, kola and coca, which they take to excess and unconsciously drift into a state which is practically equivalent to the morphin and cocain habit. Even if these drugs are not employed as the stimulant ingredients of such mixtures, unprincipled vendors so fortify innocent and mild nervous stimulants with large quantities of alcohol that the patient unwittingly becomes a slave to this intoxicant though under the impression that he is ingesting a practically harmless drug.

Some interesting statistics, recently published in *Health*, show that such habits are most prevalent in Germany, France and the United States, although they have victims in Russia, Sweden, Turkey and the Far East. The medical profession supplies 40 per cent. of the male morphinists, which is the largest proportion; after which follow men of leisure, 15 per cent.; merchants 80 per cent.; while peasants, clergymen and politicians occupy the lowest positions numerically on the list. Among the females addicted to the habit, the largest number, 13 per cent., are women of means, and these are followed in number by the wives of medical men, who make up 10 per cent. of the list.

Very recently our attention has been forcibly called to these facts by an instance which not only emphasizes these dangers but illustrates how careful a physician should be when prescribing stimulant remedies not to give the name of the preparation to the patient, or if he does so, on the prescription blank to direct the druggist not to renew the prescription without his orders. A woman, who by many years of correct living enjoyed the full confidence of her friends, was during a short convalescence directed by her physician to take a preparation of coca wine which had been very largely advertised not only to the medical profession but to the laity under a name which in no way indicates that it contains so powerful a drug as coca. Not feeling fully recovered when the first bottle of it had been consumed, the patient obtained another, and soon finding herself dependent upon it continued to purchase bottle after bottle until at the end of a year she had become a typic coca habitué. Not until she had been using the preparation for nearly nine months was her continuous use of it discovered and, when it was too late, she learned from her friends that the pleasant tasting wine which possessed these extraordinary powers, depended for its chief physiologic effects upon a drug which did not appear in its name.

So, too, at a recent meeting of the British Balneological Society, Snow drew particular attention to a form of intemperance rising from the too free administration of coca wines to invalids, whereby they obtained a strong alcoholic beverage laden, more or less, with the still more powerful stimulant coca, and it was pointed out that many women who are not above the deliberate use of such stimulants, have not the bravery to ask for alcohol or cocain in the drug store and yet do not hesitate to purchase a coca wine, or preparation of kola, under some name which does not convey, at least to their minds, the possibility of developing a habit.

There is no drug yet discovered, unless it be alcohol, which adds materially to the force of the body, and physicians can do no more goodly service to their patients than by impressing upon them this fact.

At the present time journals devoted to the subject of athletics contain, in their advertising pages, statements in regard to the action of kola and coca which are absolutely unjustifiable, and pictures are published in these advertisements which give the impression that by the use of these drugs puny men and boys may become possessed of Herculean strength. All of these remedies simply call into activity the reserve forces of the human economy and place the reserve fund of the prodigal youth at his disposal to be spent after his ordinary strength is exhausted. In a greater or less time such an individual will find that his reserve fund has disappeared and that he is a bankrupt in physical energy. It is enough that the physician must by every means in his power combat the exces-

sive use of alcohol and morphin. It is little less than a crime that greedy manufacturers should purvey to ignorant persons remedies which are capable not only of doing harm by expending the individual's strength, but which also tend to develop in him habits which sap his mental and moral development and render him a slave to the use of stimulants, and this being the case let us discourage those manufacturers and vendors who advertise such products to the laity.

PREDISPOSING INFLUENCES IN THE DEVELOPMENT OF TYPHOID FEVER.

Although we have very definite information in regard to the micro-organism which produces typhoid fever and of the fact, which has been proved beyond all doubt, that the most common means by which it gains access to the body is in food and drink, and again while we recognize that the disease can be largely prevented by the disinfection of the discharges of the typhoid patient whenever he is met with, we do not know as much as is desirable concerning those influences which predispose individuals to infection by the bacillus of EBERTH. It is also a well-recognized fact among physicians, that out of a given number of persons exposed to infection only a certain proportion will become ill because of natural or acquired immunity, but the point as to whether typhoid infection can occur through sewer gas or the inhalation of bad air from decomposing fecal matter is still a matter of dispute. In all probability the inhalation of such impure air simply decreases the vital resistance of the individual so that he is unable to withstand the attack of the micro-organisms which he has taken into his body by other entrances than that of the respiratory system.

Our attention has been called to this matter by a recent discussion before the Royal Medical and Chirurgical Society of London upon the prevention of enteric fever. In the course of this discussion after the importance of disinfection of the discharges and clothing of the patient had been considered, Dr. PAYNE expressed the belief that the theory of infection by the inhalation of the typhoid organism was worthy of credence and Dr. TIVY, who followed him, endeavored to prove that this view was substantiated by the recent epidemic of typhoid fever at Clifton, England, although Dr. DAVIES, the medical officer of health, had conclusively traced it to a polluted milk supply. Dr. TIVY asserted that this epidemic was due to sewer gas poisoning arising from want of ventilation of drains, the foulness of these drains being increased by the drought which had been present during August, September and October. As a result of this the sewer gas found its way back into the houses, especially those situated at the highest parts of the drain.

It was thought by some of those present that Dr.

TIVY's standpoint in this matter was a false one and that he had not advanced any strong reasons for his belief. In this connection, however, it is interesting to recall experiments which were made some years ago (1894) by ALESSI, an abstract of which was published in the *Centralblatt für Bakteriologie*, in 1894. In connection with his researches, made in the Hygienic Institute of the University of Rome, this investigator used rats, guinea pigs and rabbits in an attempt to determine the influence which exposure to a vitiated atmosphere would produce in rendering animals susceptible to infection. The rats were placed in a cage with a perforated bottom, and this was placed over the opening of a privy, while the guinea pigs and rabbits were placed in similar receptacles in which their own excreta was allowed to accumulate. When these animals were inoculated with a small quantity of a culture of typhoid bacillus they died within twelve to thirty-six hours, although the same dose of the same culture injected into control animals produced no injurious effect. In the animals which succumbed to typhoid infection there was found a hemorrhagic enteritis, an increase in the size of Peyer's glands and in the spleen, and typhoid bacilli in the blood, liver and spleen. The time required to produce this predisposition for typhoid infection as quoted by STERNBERG was from five to seventy-two days for the rats, seven to fifty-eight days for the guinea pigs, and from three to eighteen days for the rabbits. ALESSI also determined the fact that this increased susceptibility to infection decreased after a time. This is interesting in view of the fact that human beings also seem to become habituated to breathing an atmosphere containing sewer gas, so that they are less susceptible to infection than those who have recently arrived in the neighborhood. We think, therefore, that TIVY's belief that sewer gas may produce at least a predisposing influence is correct.

Numerous other instances in which human beings have been exposed to a vitiated atmosphere and have been taken ill with typhoid fever might be cited. These have been reported by BUDD, BOUCHARD, MURCHISON, LIEBERMEISTER, LANDOUZY and others. HENRY quotes two of LANDOUZY's cases which are of considerable interest. In one of these a man of 25 years, living in a family of ten individuals, all of whom used an identical diet and drink, slept in a room the air of which was contaminated by the ventilating pipe of a public water-closet, and suffered from typhoid fever while all the rest of the family escaped. The second case was that of a girl of 15 years who lived in a family of five individuals and was exposed to the air from a similar pipe and became ill with the disease.

Perhaps the most interesting of these cases is another one reported by W. V. KEATING in the "Transactions of the College of Physicians of Philadelphia," for 1879. In this instance four women who returned

to their home, which had been tightly closed for two months, were attacked with typhoid fever. The house was filled with a foul odor and an examination proved that the family had been "actually living in a sewer," there being no traps to the basins and the sewer gas having free entrance to the various apartments of the house.

Neither the experiments of ALESSI nor the cases which we have cited prove, as we have already stated, that typhoid infection takes place by the respiratory tract. They simply indicate that by such means a predisposition to the disease is developed, or to speak more correctly its vital resistance to a filth disease is lost.

PREMATURE BURIAL.

There are probably few persons endowed with lively imaginations who have not at some time in their lives had gruesome fancies about being buried alive, that is if the idea has ever been suggested to them. It forms the theme of many sensational tales of fiction, and is so much a matter of common belief that few would be disposed to question its possibility, or its occasional occurrence. In certain continental European cities this possibility is so fully credited that waiting vaults or guarded and watched mortuaries are kept up at public or private expense in the cemeteries, where all bodies are kept for a certain period before interment, so as to prevent any such occurrence. These are not generally so managed as to insure absolute safety from such accidents, yet they relieve the public apprehension, and may under certain circumstances be occasionally, though it must be very rarely, effective in preventing a premature burial.

In one of our English contemporaries, the *Medical Press and Circular*, there have recently appeared some articles and communications on this subject which indicate the interest the subject excites in the medical profession, as well as the difference of opinion that exists in regard to it. One writer doubts that a single well authenticated case of actual burial of a living person has ever been satisfactorily proven; others consider it not only a possible, but a much more common, occurrence than is generally supposed. From what we know of the possibilities of the trance conditions one is hardly prepared to absolutely deny that burial might occur before death, but that this has often occurred except it may be in times of panic from epidemics is questionable enough, and Dr. WALSH is justified to a certain extent in his doubts as to the evidence in the reported cases. The fact that one writer claims to have received sixty-three letters from persons who had escaped living burial is of less weight inasmuch as no details are given, and the natural love of narrating the marvelous or the unusual is a factor to be calculated with in such testimony.

That premature burial may occur, however, is in its

way a presumption that it has occurred and may happen again under circumstances that favor such a dreadful accident. The difficulty in some cases of determining whether the condition is actual death or only a suspension of the vital activities with a possibility of their full reinstatement is very great, and, it is claimed by some, is practically impossible under ordinary conditions and with the usually available means. The possibility of premature burial can therefore be reasonably admitted, and all the more so in cases of epidemics that cause general panic and hurried and unceremonial interments, and also in cases of infectious diseases occurring sporadically but which for reasons of public safety require a hasty burial. The only real universal practical test is commencing decomposition, though others are generally possible and effective, and it is therefore impossible that such an accident as the burial of a living person can often occur. The experience of the waiting or observation mortuaries in some European cities supports this view, though their continuance implies that the belief in their utility maintains itself in spite of the rarity of occasions.

The most elaborate provision against living burial is one recently announced by a Mr. CARNIS of Paris, which he calls "Karnice," and which is to render all burials provisional, as it were, for the person entombed, while still inviolate to all the rest of the world. The apparatus is to be attached to the coffin for a certain period after interment, is set in action by the least movement of the supposed corpse, while impossible to be tampered with by outside parties; it gives an alarm and admits light and air to the buried person; is cheap and easily adapted, and can be used repeatedly, so that its employment would only cost a slight rental, and a few such apparatuses would suffice for a large cemetery. If it is all that its inventor claims, it would appear to be almost an absolute safeguard against death from premature interment. On the other hand, it would seem that it might be liable to give false alarms, if by gaseous decomposition or any other cause a movement of the corpse should take place, though this might perhaps not outweigh or seriously affect its value in the minds of those fearing the accident of being buried alive. It is not improbable that many of the dislocations or derangements of bodies, found on exhumation, are due to the causes alluded to, and the possibility of their occurrence should always be taken into account.

The horror of finding oneself in a living tomb appeals directly to the imagination of every one; it seems the most terrible of all possible deaths. There is, however, another way to look at it when the physical conditions are considered. The air space in a tight coffin under five feet of earth is limited, not over two or three cubic feet at the utmost outside of the space ordinarily occupied by the body. Unless con-

sciousness returned simultaneously with respiration, asphyxia might possibly precede it and annul it—there might be some evidences of convulsion that might be interpreted as voluntary movement, but they are not necessarily indicative of such. The cases where consciousness exists throughout must be rare, though they have been made much of in fiction, and are popularly believed to be almost the rule. It is no comfort to think that any one can be buried alive, but it is better to believe, as the facts warrant us, that the long lingering death in hopeless horror, and the powerless anticipation of the fate are still less probable events.

With the modern methods of preservation of remains which are so often employed, living burial is impossible and we do not hear of any accidental homicides brought about in this way, and with reasonable delay and care the possibilities of premature interment are reduced in all cases to almost nothing, if not absolutely destroyed.

THE CAFFREY BILL.

It is noted with some surprise that the health bill introduced by Senator CAFFREY, and proposed by him in the Senate, is not the result of any medical opinion in New Orleans or in Louisiana.

It seems that the Senator was last summer stopped by some local quarantine in an obscure town in Louisiana, and found it impossible to pass through the local regulations, whereupon the Senator as soon as Congress convened, introduced a bill calculating to prevent these arbitrary actions on the part of local boards.

We are informed by competent authority from New Orleans that no medical man in that State is believed to have recommended the bill.

CORRESPONDENCE.

What is to become of the Physician?

ORAN, Mo., Jan. 24, 1898.

To the Editor:—In studying your editorial, "Is the apothecary doomed?" I am confronted with the question: What is to become of the physician? The same processes which seem to be destroying the apothecary are at work to destroy the doctor. The free dispensaries, colleges and hospitals, are gradually absorbing the patronage of physicians. No one will patronize the corner physician so long as he can get medicine and advice free at the dispensary. Some how or other I have not been very uneasy about the druggist or apothecary. I have always patronized him. Some few druggists have not treated me fairly; they have prescribed for my patrons, and I have some times filled my own prescriptions, but I never had any animosity toward druggists as a body. I dislike the substitutor or prescribing druggist, but I have always thought it necessary to have a good drug store in my neighborhood, and in order to do this I have always patronized my home druggist. I had rather make out my own prescription and have it filled by my home druggist, and I do not believe the wholesale men will gobble

up all the trade and drive the corner druggist to the wall. There is going to be a reaction one of these days. There are a great many pharmacists in this country who have not studied pharmacy with the intention of being only salesmen for big firms; they have studied with the idea of doing a business of their own and they will not sit idly down and let their avocation be destroyed. The same thing applies to us. We will not sit still and allow the hospital man to absorb our business. We will quit patronizing specialists. We will quit sending our patients to hospitals. We will organize and fight for our rights. We will not submit to monopoly. The bulk of medical knowledge today is the fruit of the country practitioner's labor. He "laid the foundation and another has built thereon." Oh, no, the wholesale manufacturer can not absorb the druggist; nor can the hospitals and free dispensaries obliterate the country practitioner. As long as the "Upper Ten" (so-called) treated us fairly we submitted kindly to his pretense of superiority, but when he assumes the right of absorbing the whole business by the tricks of trade and a cut in prices, or any other underhanded trickery, he will find one of the most vigorous kicks coming imaginable. The druggist and practitioner were once true friends and their interests were the same, and when they see that there is a plan being formed to exterminate them, rest assured they will not submit to it. Nicely prepared tablets, triturates, or what not, can be prepared by one capable of making them at all, one place as well as another, and the corner druggist does not have to give up his business and hire out, neither does the country practitioner have to appeal to his city brother for aid. He can do as the pioneers did before him. He can perform his own surgical operations and leave the specialist to hunt up his cases wherever he can find them. If the wholesalers understand their position and how they obtained it, they had best look a "leedle out." Do not shove us too near the wall. We have some rights that must be respected. A word to the wise ought to be sufficient.

Respectfully, W. P. HOWLE, M.D.

"Foreign Medical Training for Recent Graduates."

ELIZABETH, ILL., Jan. 18, 1898.

To the Editor:—In an article written on the above subject by W. S. Caldwell, M.D., from Vienna, the writer would like to take a few exceptions. Quoting from Dr. Caldwell's article in the JOURNAL of Jan. 15, 1898: "Not because the subject is better understood or more skilfully taught than by our best teachers, but because the clinical material is much more abundant here and can be much better utilized for clinical purposes, and the number of those to be taught are much fewer in proportion to material available." Also: "There may be just as good courses as these at home, but I have not been able to avail myself of them for I have not been able to find them." I simply wish to say that I for one have found "just as good courses as these at home," and though I have not myself enjoyed the "merits of Vienna" (?) I have enjoyed personally Czerny's clinic of Heidelberg and Schede's clinic of Hamburg, in the "Neuen Allgemeinen Krankenhaus." My parents being of German birth, I of course had the German language at my command, so that my observations could not lack for want of this advantage to read and speak German. All the advantages enjoyed at Vienna and Paris, as given by Dr. Caldwell, are enjoyed at the Medical Department of the Tulane University of Louisiana, located at New Orleans; also at the New Orleans Polyclinic like advantages are to be obtained. These places of learning have at their disposal all the clinical material of the Charity Hospital, as they think best for teaching purposes. The proportion of medical students (in 1891 number 374) in proportion to the clinical material at hand

compares with any, as the records of the hospital will show that during 1891 a grand total of 23,537 patients were treated. Medical students spend half of each day in the hospital for the clinical study of disease and to treat the same under the guidance of equally as great instructors as those mentioned by Dr. Caldwell.

Who that has had the advantages of these instructors at this institution will not remember with pride, the venerable dean, Professor Chaillé, who taught us (diagnosed with us) our first lesson in diagnosis and in pathologic anatomy. In clinical medicine who does not think of Professor Elliot and Professor Joseph Jones. In surgery, how well T. G. Richardson, Edmond Souchon, Samuel Logan and Albert Miles will compare. True, some of these are gone before us, but in their place we find others equally pure in the faith, as Rudolph Matas, etc. I have mentioned names because Dr. Caldwell brings forth names to worship, and why not worship our own heroes. I am convinced that in our medical centers in this country, we are equal in every respect. I specially mention the Medical Department of the Tulane University and its equal advantages, because I personally know that the clinical advantages at the New Orleans schools are not surpassed anywhere, and especially not in clinical or internal medicine. The Louisiana State law confers this privilege on the medical profession, to properly educate doctors. And again, if Dr. Caldwell prefers the "French professors," he will find a "French born teacher," who "explains every step of his operation," in the personage of Professor Souchon, in the above Medical Department of the Tulane University, who is professor of surgery and learned to his finger tips. There may be other schools in this country equally as well prepared to stand equal in any branch of medicine, so that "recent graduates," undergraduates and old doctors need not cross the sea to get superior medical information.

PHILIP ARNOLD, M.D.

Do Adult Squirrels Castrate Each Other.

CHICAGO, ILL., Jan. 25, 1898.

To the Editor:—In the article on eunuchs in the previous number of the JOURNAL I stated that when adult gray squirrels engage in battle one often castrates the other. I had this information from a distinguished naturalist, who inferred it because a considerable portion of wild squirrels are found to be emasculated.

Dr. A. S. Allen, an interne of Mercy Hospital, Chicago, furnishes the following facts observed by him which partly contradict the naturalist.

Dr. Allen says that although about one-third of the wild squirrels killed by hunters are found to be castrated, yet he thinks it is not done in fighting. He says that a number of gray squirrels lived protected in the trees about his former residence. A female raised a litter of young in a tree close to the house. One day when the young were about one-quarter grown he observed the male trying repeatedly to enter the nest, but the female, which in that species is the largest of the two, fought him off and drove him away. This repeated several times, and the male finally desisted. Some time later the female went away apparently to gather food. Before she returned the male reappeared, entered the nest and created a great disturbance there, so that the Doctor climbed the tree and examined the young. He found four young quarter-grown males and one or two females. Three of the young males had been freshly castrated, the old male squirrel having bitten their scrotum and testes cleanly and smoothly off with his sharp incisors.

In a fight between two full grown males it would seem very difficult for either to hold the other still enough to admit of biting off his scrotum, but the young are more helpless; hence

it is probable that all the castrated squirrels taken by hunters are mutilated in infancy by the old males. It is a curious instinct and one difficult to account for by natural selection, since it would not seem to result in the escape of the strongest nor the fittest from mutilation, and consequently would hardly tend to benefit or perpetuate the species.

Dr. Allen says in all his hunting he never found a fresh castration wound in an adult, so that he believes the operation is done only on the very young. He is of the impression that the castrated ones grow larger, and are apt to be fatter than the perfect males.

EDMUND ANDREWS, M.D.

Leprosy in Norway.

NEW YORK, Jan. 8, 1898.

To the Editor:—Under "Leprosy in Norway," Dr. W. S. Caldwell writes to the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Dec. 18, 1897: "Speaking to my host (Hansen's first assistant) in a congratulatory tone of our almost entire exception from the disease in the United States, he answered me warmly and decidedly, saying: 'You have plenty of lepers in your country, but your physicians do not recognize the disease, and allow the patients to run at large, while here in Norway we diagnose the malady in its early stages and isolate the patients.' In a late visit of Dr. Hansen to the United States, he told me that the Doctor found three cases in the hospitals in Chicago, and twice as many in New York, as well as encountered several cases of true leprosy upon the streets of each city, all of whom were being treated for lupus, syphilis or some other form of skin disease."

This direct slap by a Norwegian physician (Hansen's first assistant) at the intelligence of American physicians is in keeping with what we know of the general behavior of the Scandinavian sages toward ordinary medical mortals. I know from the most creditable source, that these flattering opinions were expressed to the whole medical world, as far as it was assembled at Berlin, and produced a general feeling of disgust: "Norway is interested in the leprosy question only as the world's teacher; she has nothing to learn." This truth was continually flaunted in the face of the Conference, whosoever does not recognize and appreciate the superiority, in point of leprosy, of these superior instructors, is stupid, and stupid people, as one of them frankly told me, ought not to be helped, they do not deserve it.

I venture to affirm that not only the ordinary practitioners of those parts of our country where the Norwegian immigrants stop, are the superior of the general practitioners of Norway in every way, but that the medical men of our large cities (New York and Chicago are quoted) *do not* diagnose the leper as lupus, syphilis or some other form of skin disease, as Hansen is reported to have told his first assistant.

Is your correspondent quite sure of his statement that Hansen mentioned such errors of diagnosis in the large hospitals of New York and Chicago? If he visited these hospitals there were American physicians with him, who might now come forward and confirm or deny the accuracy of Hansen's assertions.

ALBERT S. ASHMEAD, M.D.

Department of Public Health.

CHICAGO, ILL., Jan. 11, 1898.

To the Editor: I have been reading with interest the various notices in the JOURNAL relative to the establishment of a Department of Public Health at the National Capitol and the furtherance of such legislative enactments as will tend toward the preservation of the public health. Early in 1893 I advocated such measures and devoted attention to the question in a treatise on Asiatic cholera written and published by me in that year. There is one pronounced element of danger in connection with the favored change and to this I would respect-

fully call the attention of my professional colleagues. This is the fact that peradventure some "practical politician" would be made the Secretary in charge of the new portfolio instead of a medical hygienist.

The ridiculous and unfortunate state of affairs that would be induced under these circumstances need hardly be dilated upon. The proper person to fill the new position must be a physician, and he must be a physician who is high authority on questions connected with preventive medicine.

JOHN A. BENSON, M.D.

Professor Physiology of the Nervous System in the College of Physicians and Surgeons, Medical Department State University, and Professor of Psychologic Jurisprudence in the Chicago School of Law.

The Antivivisection Bill—Necessity for Action.

BALTIMORE, Jan. 17, 1898.

To the Editor:—I hope that the JOURNAL will keep up its campaign against the antivivisection bill in the Senate (1063). I am writing letters to the physicians in different States urging them to write themselves and induce others to write to their senators urging them to oppose the (Gallinger) bill. Personal letters from those known to have influence with senators will accomplish more at present than protests from societies. Would it not be worth while to call attention in the JOURNAL to the importance of such personal appeals to senators?

Very sincerely yours, W.

Indiana State Medical Society.

INDIANAPOLIS, Jan. 24, 1898.

To the Editor:—Owing to a delay in rebuilding the leading hotel of Evansville, the profession of that city have decided that it would be unwise to attempt to hold the annual meeting of the Indiana State Medical Society there this year. At a meeting held today in the office of the president, Dr. W. N. Wishard, attended by the officers and chairmen of the various committees, it was voted unanimously to transfer the meeting to Lafayette. The date remains unchanged, May 5 and 6.

By kindly giving this notice a place in your paper you will confer a great favor upon the profession of Indiana.

Very respectfully, F. C. HEATH, M.D.

Must Join State or Local Society.

GLENWOOD SPRINGS, COLO., Jan. 19, 1898.

To the Editor:—Is it compulsory for me to belong to a medical society, either local or State, before I can join the AMERICAN MEDICAL ASSOCIATION? We have a State but no local medical society.

Yours truly,

L. A. ROBINSON, M.D.

ANSWER:—The bylaws require that membership by application can be obtained only by having the application certified by the president and secretary of a local or State society in affiliation with the AMERICAN MEDICAL ASSOCIATION.

Concerning an Alleged Birthmark, "Snake" eye.

MILWAUKEE, WIS., Jan. 18, 1898.

To the Editor:—There are several thousand physicians in this country and no doubt several hundred who may be reached within an hour or so of travel from the office of the gentleman in Waukegan, Ill., who are capable of properly cataloguing his case of "snake" eye within some one of the not uncommon congenital anomalies, probably congenital coloboma or fissure of the iris. If the Doctor would give the lad the benefit of a consultation with an oculist, he would not only learn something but help his "myopic" patient whose "eyes are elongated antero posteriorly."

Courteously yours, H. V. WÜRDEMANN, M.D.

The Yellow Fever Microbe.

NEW ORLEANS, LA., Jan. 22, 1898.

To the Editor:—*New Orleans Medical and Surgical Journal* for February, 1898, will contain an article upon the "Serum Diagnosis of Yellow Fever," by Archmaid and Woodson of New Orleans, La. These observers, working in the laboratory of the Louisiana State Board of Health, report the occurrence of a characteristic agglutinative reaction of yellow fever blood with the bacillus icteroides in over 70 per cent. of a series of fifty cases with which the experiments were conducted. They consider the reaction of decided value in the diagnosis of early mild and atypic cases. Yours very truly,

R. S. W.

ASSOCIATION NEWS.

Prof. Samuel C. Busey, who was elected to deliver the annual oration on State Medicine, has resigned the position. The members will learn this with regret, and also that the ill-health of Professor Busey was the cause of his resignation.

Section on Materia Medica and Therapeutics.—The following papers and discussions have been promised for the meeting at Denver, Colo., June 7-10, 1898:

Yellow Fever: discussion by Surgeon-General Geo. M. Sternberg of Washington, D. C.; Prof. John Guiteras of Philadelphia, Sollace Mitchell of Jacksonville, Fla.; T. S. Scales of Mobile, Ala.; G. B. Thornton of Memphis, Tenn., and H. M. Bracken of Minneapolis, Minn.

Aims of Modern Treatment of Tuberculosis, by Prof. Edwin Klebs of Chicago.

Serum Therapy of Tuberculosis, by Prof. S. O. L. Potter of San Francisco.

The Use of Remedies in Diseases of the Heart and Blood Vessels, by T. Lauder Brunton, M.D., D.Sc., F.R.S., London, England.

The Mescal Button, by Prof. D. W. Prentiss of Washington, D. C.

The Modern Intestinal Antiseptics and Astringents, by Wm. Frankhauser, New York.

To What Extent is Typhoid Fever Favorably Modified in Its Course, Duration, Termination or Sequelæ by the Administration of Drugs, by Frank Woodbury of Philadelphia.

Strychnin, by J. N. Upshur of Richmond, Va.

Methods of Teaching Materia Medica and Therapeutics, by Prof. G. H. Rohé of Baltimore, Md.

The Use of Electricity by the General Practitioner, by Caleb Brown of Sac City, Iowa.

J. E. Atkinson, Baltimore; Henry Beates, Philadelphia; T. M. Balliet, Philadelphia; Geo. F. Butler, Chicago; J. Solis Cohen, Philadelphia; N. S. Davis, Jr., Chicago; P. J. Farnsworth, Clinton, Iowa; E. D. McDaniels, Mobile, Ala.; J. E. Moses, Kansas City, Mo.; Jos. Remington, Philadelphia; L. E. Sayre, Lawrence, Kas.; H. V. Sweringen, Fort Wayne, Ind.; E. L. Stephens, Fort Worth, Ind.; Leon L. Solomon, Louisville, Ky.

The Chairman will be pleased to receive and place upon the program subjects for discussion and papers.

JOHN V. SHOEMAKER, Chairman,
1519 Walnut Street, Philadelphia, Pa.

SOCIETY NEWS.

The Kalamazoo Academy of Medicine of Kalamazoo, Mich., met in annual session in their rooms Jan. 4, 1898. The Society's rooms are in the Public Library Building, a gift to the city of Kalamazoo by Dr. E. H. Van Deusen, a member of the Academy, and as a meeting place for a medical society, will compare favorably with the rooms of any similar organization in any of the metropolitan cities. There were eighty-six members pres-

ent at the afternoon session. The report of the secretary showed 105 active and 18 corresponding members and 1 honorary member. The treasurer's report showed a good working balance. In the afternoon the following papers were read by the writers: "The Newer Surgery of the Radical Cure of Hernia," by Dr. E. Wyllis Andrews of Chicago; "Toxic Amblyopia," by Dr. Fleming Carrow of Ann Arbor; "The Regular Profession of Medicine," by Dr. W. H. Haughey of Battle Creek. At the evening session Dr. J. M. Elliott, the retiring president, gave an address, which was followed by a banquet at the American Hotel. There were seventy-six members present at the banquet. The following officers were elected for the ensuing year: President, William M. Edwards; first vice-president, J. M. Rankin; second vice president, Wilbur F. Hoyt; secretary, A. D. Lake; treasurer, O. B. Ranney; librarian, E. H. Van Deusen; censors for three years, F. C. Myers and C. W. Huff.

At the Annual Election of the New York Medical League Jan. 14, 1898, the following officers were chosen. The medical profession shows the greatest and meanest of followers, and unfortunately, the latter have had too much influence, from the simple reason that the bad are always active and the good passive. The League believes that the profession can be restored to its former high position and the names of the officers for the year are sufficient evidence of the earnest and determined opposition which awaits the schemes of the treacherous and the self-seeker. Manhattan Section New York Medical League: President, Joseph E. Janvrin; vice-president, Frederick R. Sturgis; recording secretary, J. C. Schminke; corresponding secretary, Douglas H. Stewart; treasurer, E. Eliot Harris; trustees, Frederick H. Wiggin, E. J. Gallagher, S. Kennedy; finance committee, W. H. Weston; executive committee, J. Smith Peterson, J. E. Messenger, George D. McGauran, Wickes Washburn; delegates, Adolph Rupp, Heinrich Stern, Joseph H. Byrne.

PUBLIC HEALTH.

The results of Sanitation in the German army for the period of the past thirty years show that twenty-three thousand fewer men fall ill every year than formerly and that twenty-two hundred fewer die.

Loomis Sanitarium for Consumptives.—On January 15 a training school for nurses was opened at the Loomis Sanitarium, Liberty, N. Y. The opening class had thirteen members. While these nurses will receive regular training such as is given in other schools, special attention will be paid to instruction in the care of cases of tuberculosis. This departure in the way of nursing is a new one, and is justified by the ever increasing demand for nurses for this class of patients. It is believed that these nurses can be constantly and advantageously employed in health resorts and as traveling companions for young people in incipient stages of the disease. The course will be of two years' duration.

Still the Plague.—The fighting in India has monopolized the attention of the racialists of at least one hemisphere so that plague ravages in Poonah, Bombay and the Deccan have passed unnoticed. Thousands have fled from Poonah and Bombay, in each of which cities the weekly mortality is from five hundred to six hundred. The aid of the military has again been invoked. Poonah City is divided into ten wards, and in each ward an officer has thirty soldiers under his command. Every morning the plague centers are cordoned. No one is allowed to leave them except after having been medically examined. In the mean while each house is searched, and the plague-stricken are taken to the hospitals and their houses are disinfected and whitewashed. This system is working well, and

the outlook is improving. A report of the epidemic in Damannu, Portuguese India, with the verification of the London *Lancet*, December 18, gives cheerful accounts of the value of inoculation lymph, chiefly among the Parsee community, who at an early stage acquiesced. Between March 26 and the end of May, the uninoculated furnished a mortality of 24.6 per cent., while the ratio of the inoculated was 1.6 per cent. The demand for lymph necessitated the substitution of the weaker article for the stronger and gave a decided accentuation in favor of the latter. Still even there the case mortality showed a corresponding wavering against the expectant treatment.

The Relations of Medical Societies to the Public Health. The Presidential address of Dr. Edward Seaton, before the Society of the Medical Officers of Health of Great Britain, considered the subject of the work of the medical societies in its relation to public health. Much of the work of the pathologic, medical and clinical societies, and the unremunerated researches of individuals, whether undertaken in a purely scientific spirit or with an immediate utilitarian motive, had contributed greatly to the promotion of the ends which their society more directly or exclusively had in view. But the Epidemiological Society, which occupied a position intermediate between the strictly medical societies and their own, was above all others engaged, as its objects stated in the charter of incorporation showed, in pursuits identical with theirs. Then there were the British Institute of Preventive Medicine, the Sanitary Institute, the Institute of Public Health, the Jennerian Society, and the British Medical Association, which, though primarily a union of medical men, had a public health section at its annual congresses. The Sanitary Institute and one or two others embraced men of all professions more or less interested in public health, and there was no doubt that much advantage accrued from association with architects, engineers, chemists, geologists, etc., as well as from the museums and exhibitions promoted by some of these societies. Their various transactions and journals were of great value, yet members of their own society who belonged also to the Epidemiological Society and the Sanitary Institute could not but consider that the multiplication of societies involved a loss of power. The Maidstone epidemic had shown how different was the sanitary examination of water-supplies from the merely chemic question of the analysis of adulterated foods and, also, how important was a knowledge of the normal condition of a given water and of the contingent dangers to which it was exposed apart from actual contamination. Chemic analysis, without bacteriologic examination and other considerations to which he had alluded, might tend to a false sense of security, but taken in conjunction with these it should serve as a delicate barometer and an indication of impending danger. But while such catastrophes aroused public attention owing to their suddenness, it ought to be known that there was in some districts a constant prevalence of typhoid fever attributable to other causes than the pollution of a certain public water-supply, and the record and publication of the distribution of any local excessive incidence of this and of other preventable diseases, as was done by the Surrey County Council, by stimulating preventive action contributed in an important degree to the averting of such outbreaks and to the saving of life without the supervention of those terrible lessons. Such a society as he had indicated should include all the leading epidemiologists who, without belonging to the public service, had made the subject of communicable diseases their special study, and its inauguration would, he repeated, be a fitting and worthy commemoration of the jubilee of the institution of medical officers of health. *London Lancet.*

A Serious Epidemic of Typhoid Fever Due to a Contaminated Water Supply. All England has been excited and concerned by the epidemic of typhoid fever which is attracting so much attention at Maidstone, Kent. There have been 1,700 cases in that town and its vicinity and fifty deaths have occurred. The epidemic has spread at the rate of 120 cases daily, and the authorities are working energetically in their efforts to crush out the fever. The hospital accommodation is inadequate, temporary hospitals are being erected and the schools are being

converted into sick wards. There have been numerous cases of typhoid fever throughout the country among people who recently visited Maidstone. The town authorities of that place are held responsible for the outbreak, owing to their refusal to renew the appointment of a watchman for the water supply at a salary of \$200 yearly. Quite a number of difficult conditions have been surmounted by the authorities. The fitting up of emergency hospitals has been no light task. The houses and school-rooms utilized had not the necessary sanitary conveniences. The work had to be continued day and night without a moment's respite. Nor was it easy to get together some three hundred beds for the patients and to lodge more than one hundred nurses. Then the patients and nurses had to be fed, and this involved the organization of a commissariat department which was altogether out of the ordinary attributes of local administrative work. But soon another difficulty arose. A large amount of linen accumulated which was dangerously soiled by the patients. If this linen was scattered over the town and washed anyhow and by anybody the consequences were likely to be very serious. The medical officer of health, Mr. Matthew A. Adams, thereupon conceived the idea of establishing a public laundry for dealing exclusively with the infected linen. With the very efficient aid of Mr. Jackling, the sanitary inspector, a steam laundry with all the most recent and improved machinery was promptly opened. Carts are now sent around the town with numbered canvas bags. The linen from each patient is placed in a separate bag, distinguished by its number. On reaching the laundry the bags without being opened are plunged into a large boiler, where their contents are thoroughly disinfected by prolonged boiling. Then only are the bags opened and each article marked with a number corresponding with that of its bag. The articles can be washed in the ordinary manner. But so great is the amount of work that had to be done that it was necessary to establish four large boilers set in solid brickwork, and to put up huge tents seventy-five feet in length in which the linen is sorted. Another great difficulty soon arose. How was so large a quantity of linen to be dried? Fortunately, in a field opposite there were two roast houses for the drying of hops. These curious looking, cone shaped structures are familiar to all who travel in hop-growing countries. In the lower part there is a furnace where smokeless anthracite coal is burnt. Above the furnace and just under the cone-shaped roof there is not a floor, but horse-hair matting resting on rafters. It is on this matting that the hops are placed to dry, as the heat passes through readily. For laundry purposes it was necessary to construct a framework all around the roof above this matting so as to hold ropes or poles on which the linen is hung to dry. The *Lancet* states that an official inquiry has been ordered, so that the blame may be located. No doubt the water company will be incriminated in the first instance and the local authorities will be held blameworthy for the prolonged continuance of the epidemic. The later reports of the medical officer of the Local Government Board record epidemics which prove incontestably that the grossest and most culpable neglect prevails as regards a number of our public water services, whether the supply is derived from springs, deep wells, gathering grounds or streams; and we fear that at times the extent of the negligence and danger bears a definite relation either to the amount of pecuniary profit actually derived from the sale of the water to the public or to efforts made to render the profit greater. This is a state of affairs which has hitherto been all but ignored by parliament in granting powers to water companies, whether municipal or private, and it is to be hoped that the attention which has been drawn to the subject by the Maidstone epidemic will lead to a much more careful watch than has usually been exercised over the powers and liabilities conferred and incurred in bills as to public water supplies. The population of Maidstone Borough is estimated at about 32,000.

NECROLOGY.

EDMUND CARLYLE VERMEULEN, M.D., College of Physicians and Surgeons, New York, 1860, died in Philadelphia, his home, January 21. He was the son of a Dutch Reformed clergyman

and was born in New York City in 1833 but lived in Hoboken, N. J., where he had been an apothecary previous to his graduation in medicine. After a competitive examination he was appointed as Assistant Surgeon, U. S. N., Nov. 16, 1861 and rose to the rank of Master Jan. 24, 1862. He was in active service throughout the war with a record of executive ability and served at various naval stations until 1882 when he was retired. It is told that while serving on the *Granite City*, the vessel with all the officers and men were captured by the Confederates. He was a prisoner four months. His health had been poor for some years before his death.

CORNELIUS VAN KEUREN, M.D., died at his residence in New York City, January 21. He was born in old Greenwich village, once a section of the city where the Holland Dutch element was somewhat prominent. At the out-break of the war he joined Duryea's Zouaves and was mustered out at the expiration of his term of enlistment. In 1874 he received his degree from the College of Physicians and Surgeons, New York, and many years ago was appointed a surgeon in the Police Department, retiring with a pension, last October.

CAROLINE M. DODSON, M.D., Woman's Med. College, Philadelphia, 1874, died January 9. She was born in Keosauqua, Iowa, 1845, and after graduation at once entered the profession in Philadelphia. As a platform speaker on educational and temperance topics she soon became conspicuous. In 1891 she became president of the Woman's National Health Association, without a surrender of her work in the Woman's Suffrage Association or of her interest in the Baptist Sisterhood and Sabbath school teaching.

ERNEST RINGER, M.D., a licentiate of the New York County Medical Society, 1874, died at his home in New York City January 9. A native of Germany, with a university education, he came to this country about fifty years ago, and here continued in practice until within about ten years of his death at the age of 77 years. At one period of his life he was a medical writer, holding somewhat peculiar views upon therapeutics.

WILLIAM H. ROBB, M.D., Albany, N. Y., 1865, of Amsterdam, N. Y., died January 12 in Selma, Ala., aged 54 years. He was a prominent member of the AMERICAN MEDICAL ASSOCIATION and a fellow of the New York State Medical Association, of which he was one of the founders. His illness began at the annual session of the latter association last October, and with an attack of influenza subsequently superadded, put him beyond the possibilities of ultimate recovery. A popular citizen, judicious sanitarian, and valued contributor to medical literature, his place can not well be filled.

ORANGE W. BRAYMER, M.D., Jefferson, 1888, member of the surgical staff of the Cooper Hospital, Camden, N. J., died from blood poisoning January 9. The cause was thought to be due to an inoculation of a scratch upon the forehead after an operation at the hospital performed by him about two days before.

LEWIS W. PENDLETON, M. D., Albany, N. Y., 1864, of Portland, Maine, and house physician of the Flagler Hotel, Florida, died at the Palm Beach Inn, Jacksonville, Fla., January 12, aged 53 years.

HENRY S. DEAN, M.D., Jefferson, 1852, born in Holland, Mass., died January 14, aged 74 years. He began practice in South Coventry, Conn., and there resided until his death. He was an active member of the Connecticut State and of the Tolland County Medical Society, besides having served in the Connecticut General Assembly in 1872-3.

C. E. ULMER, M.D., died in Atlantic City, N. J., of tuberculosis, aged about 40 years, on January 15. He was at one time county physician of Atlantic County, N. J.

F. R. V. SCHNEIDER, Vienna, aged 85 years. A laboratory accident in 1871 injured both eyes and arrested his brilliant scientific career as professor of chemistry, etc., investigator and author of works on chemico-legal and hygienic questions.

Since then he has occupied a prominent position in sanitary and hygienic councils, his services winning him many honors, among them a title and seat in the legislature.

SAMUEL P. HARNED, M.D., N. Y. University, 1868, for many years Township physician, died at his home in Woodbridge, N. J., January 18.

HENRY S. DEAN, M.D., South Coventry, Conn., January 15, aged 74 years.—F. K. Hall, M.D., Pittsburg, Pa., January 12, aged 71 years.—W. C. Nixon, M.D., Shannon, Ga., January 13, aged 55 years.—J. H. Otto, M.D., Milwaukee, Wis., January 15, aged 36 years.—W. H. Robb, M.D., Amsterdam, N. Y., January 12, aged 54 years.—William Henry Sibert, M.D., Kansas City, Mo., January 13, aged 48 years.—J. C. Thompson, M.D., Rollersville, Ohio.—J. W. Waters, M.D., Lexington, Ill., January 15, aged 70 years.—James F. Barron, M.D., Clinton, Ga., January 18, aged 70 years.—C. E. Ulmer, M.D., Atlantic City, N. J., January 15, aged 40 years.—Lysander T. White, M.D., Cortland, N. Y., January 16, aged 55 years.—Angel Vasquez, professor of organic chemistry and pharmacy at Santiago, Chile. A physician and hygienist of national prominence.—C. B. Day, M.D., Glencoe, Minn., January 13.—J. C. Thompson, M.D., Rollersville, Ohio, January 4, aged 76 years.

ORANGE W. BRAYMER, M.D. At a special meeting of the District Medical Society of Camden County, N. J., held January 10, the following was adopted:

We, the Camden District Medical Society assembled, called together by the sudden death of our esteemed associate, Dr. Orange W. Braymer, do hereby acknowledge, with mingled grief and humility, our child-like misapprehensions of such transitions in life.

While yet in the full vigor of his professional manhood, and while attending the surgical needs of a suffering patient the Angel of Death appeared, and very soon carried him to the bourne "Where his weary brain and tired feet, will no longer brave the midnight summons, nor attend the calls of a poor suffering humanity."

Need we recall his manly form and earnest kindly face, or rehearse his many deeds of charity, and devotion to his profession, to remember him. Nay, it is well known by those who knew him best, that his illy-requited devotions to his profession and his patients, his faithful friendships, and conscientious performance of all duties, indicated his true nobility and reflected honor upon us, as well as upon his family, church and State. His life is worthy of emulation, and may its impress be indelibly stamped upon our tablets of memory.

His bereaved family, crushed by the sudden loss of an affectionate husband and father, can obtain consolation alone from that God who as Divine Ruler of the Universe, "knows best how to give, knows best when to take away."

Therefore, as a slight token of esteem and love for our dead, be it hereby

Resolved, That these sentiments so well engraved upon our hearts, be recorded upon the pages of our Society's history and also transmitted to his grieving family as a memento of our sympathy, and be it further

Resolved, That we attend in a body the last sad rites upon our dead brother, and bow with submission and humility to the will of God our Creator.

O. B. GROSS, M.D.
J. M. RIDGE, M.D.
D. BENJAMIN, M.D.
JOS. H. WILLS, M.D.
E. E. DE GROFFT, M.D.
Committee.

BOOK NOTICES.

Transactions of the Medical Society of the State of North Carolina. Paper, pp. 184. Illustrated. Wilmington, N. C. 1897.

This volume is on excellent paper, well edited and of excellent typography, and contains full proceedings of the forty-fourth annual meeting, held at Morehead City, N. C., June 8, 9 and 10, 1897. Among other papers included we note: "When to Operate;" "Surgical Treatment of Hemorrhoids;" "A New Method of Dealing with Inoperable Cases of Cancerous Affections of the Uterus;" "The Ideal Antipyretic;" "The Key-

stone of the Medical Arch;" "The Microscope in Diagnosis of Malaria;" "An Interesting Case of Appendicitis;" "A New Treatment of Hydrophobia: Report of a Case: Recovery" "Psycho-therapeutics;" etc. An appendix of 48 pages includes the Constitution and By-laws and the Code.

Transactions of the Luzerne County Medical Society, for the year ending Dec. 31, 1897. Paper, pp. 208. Wilkesbarre, Pa. 1897.

The contents of this volume comprise: "The Hygiene of the Jews;" "Progressive Pernicious Anemia;" "Diabetes;" "Intubation and Antitoxin in Membranous Croup;" "The Modern Conception of the Nervous System;" "Operative Interference in Epilepsy;" "Discussion of Measles;" "Fracture of Skull and Treatment;" "Treatment of Phthisis;" "Mastoid Disease Followed by Sinus Thrombosis, Meningitis and Death;" "Traumatic Neurosis;" "Placenta Previa;" "Cerebral Localization;" "Double Consciousness;" "Serum Therapy;" "The Proposed Sanitarium for Tuberculosis at White Haven;" "Hematozoön Malariae;" "Tetanus;" "Acute Diseases of the Heart;" "Syphilis," and "The Theory of the Extension and Retraction of the Neuron Terminal." The excellent paper and typography make this volume a credit to the Society.

Transactions of the Arizona Medical Association. Paper, pp. 66. Phoenix, Ariz. 1897.

This volume covers the work of the sixth annual session of the Arizona Medical Association, held at Phoenix, Arizona, January 26, 1897. Eleven papers are included.

Transactions of the Mississippi State Medical Association. Paper, pp. 212. Illustrated. Biloxi, Miss. 1897.

Besides the usual reports, etc., found in society transactions, this volume contains the Constitution and By-laws of the Society and the papers read at the twenty-ninth annual session, held at Vicksburg, Miss., April 15, 16 and 17, 1896, twenty-three in number, some with illustrations.

Kalender fuer Frauen- und Kinderärzte. Von Dr. Med. EICHHOLZ, Bad Kreuznach, und Dr. Med. SONNENBERGER, Worms. 11 Jahrgang. 1898. Kreuznach: Ferd. Harrach. Preis. Mk. 2.50.

This wallet-shaped leather bound volume contains memorandum pages for each day of January, February and March, tables of drugs and doses, pages for filling out with data concerning the patient, numerous short articles descriptive of diseases peculiar to women and children, Prussian rules for physicians, etc., altogether making a handy and valuable compilation for the physician. The matter is printed in German. Three supplements contain memorandum pages for the months April-December, 1898.

MISCELLANY.

Dr. Robert T. Wilson is to succeed his father, Dr. H. P. C. Wilson, as chief surgeon of the Woman's Hospital, Baltimore, Md.

A Change of Name.—The British Institute of Public Health will be styled in future the Royal Institute of Public Health, and Queen Victoria has accepted the office of patron.

Last Year's German immigration shows a wane. In 1897 it was the lowest since 1874. It aggregated only 23,220 against 32,114 in 1896 and has declined steadily since 1893, when 87,577 left Europe.

Honors After the British Jubilee. The honor of Knighthood has just been conferred by Queen Victoria on Dr. John Struthers, late president of the Royal College of Surgeons of Edinburgh, and Dr. John Batty Tuke, president of the Royal College of Physicians of Edinburgh. Professor Gardiner, dean of the Faculty of Medicine, Glasgow University, has been promoted to be Knight Commander of the Order of the Bath

(K. C. B.), and Professor D'Arcy Thompson, British delegate at the recent conference on the Behring Sea Fisheries, has been appointed a Companion of the same order (C. B.).

The Determination of Sex Theory, associated with the name of Professor Shenck, does not find much favor with savants. With the qualifying *ifs* and the usual loopholes of explanation in problems of the 50 cent. variety, not much can be expected. "Guess," said Sambo, "boy or girl?" "Boy?" "No, guess again." "Then a girl." "Yes, but who told you?" It is to be hoped that we are to have no more depopulating agencies, remote or otherwise.

The Hoff Memorial Fund.—Maj. John Van R. Hoff, surgeon U. S. A., now on duty at Vancouver Barracks, offered to establish a memorial fund for the late Alexander H. Hoff of the medical department of the army. The Secretary of the Treasury has accordingly been authorized to accept from Major Hoff the sum of \$1,000 for interest at 4 per cent. The interest accruing from the fund is to be expended under the direction of the chief medical officer of the army for the purchase of a suitable gold medal each year, to be awarded to the graduate of the Army Medical School who maintains the best average standing in class. In case there is no session of the school in any year, a suitable medal is to be secured and presented to the medical officer of the army who during the year shall have performed the most distinguished medical research.

"In Good Health."—The United States circuit court of appeals says, in the case of the Manhattan Life Insurance Company vs. Carder, Nov. 10, 1897, that the term "in good health" is comparative. It does not mean in perfect health, nor would it depend upon ailments slight and not serious in their natural consequences. In construing this term in a life policy, the court goes on to say that it must regard the character of the risk assumed, and that looking at it from this point of view, it would seem that a person was in good health unless he was affected with a substantial attack of illness, threatening his life, or with a malady which had some bearing on the general health; not a slight illness or a temporary derangement of the functions of some organ.

The Bacillus of Whooping Cough.—Advices from Europe announce that Dr. Czapelewski, the celebrated bacteriologist of Cologne, has confirmed the discovery of bacillus of whooping cough recently made by Dr. Henry Koplik of New York. Dr. Koplik has been experimenting with particular relation to whooping cough for four or five years. A paper on the discovery of the bacillus was read before the British Medical Society in Montreal last summer. The bacillus is an exceedingly small and delicate one. In fact, with the exception of that of influenza, it is the smallest yet discovered. Its size is really about the same as that of influenza. Animal experiments have been tried, but it has been found impossible to reproduce the disease in animals.

Explanation of the Beneficial Effect of Venous Stagnation and inflammation in the struggle of the organism against the invasion of microbes.—Professor H. J. Hamburger announces that it is due to a hitherto unknown factor: the property possessed by CO₂ of causing the red and white corpuscles to swell up, and of liberating a diffusible alkali from the albuminates. It has already been established that serum taken from stagnated venous blood is much more bactericidal than normal blood, and that the lymph is also more bactericidal when stagnated. This he proves is due to the accumulation of CO₂. His tests showed that serum treated with CO₂ was far more bactericidal than normal serum, and that the richer in alkali the more pronounced the effect. Inflammation also causes stagnation, and hence the same effects; an accumulation of CO₂ in the parts involved and increased bactericidal power. He also asserts that the bactericidal properties are more pronounced the larger

the number of white corpuscles present, which affords a new explanation of the *pus bonum et laudabile* of the older pathologists. The cells of the lymph glands also evince the same disposition to swell up and liberate alkali under the influence of CO₂.—*Deutsche Med. Woch.*, December 2.

What May be Assumed in Hypothetic Questions.—In the direct examination of an expert witness the facts assumed in a hypothetic question should be only such as are fairly within the scope or range of the testimony. Upon cross-examination, however, the supreme court of Illinois holds, in *West Chicago Street Railway Company v. Fishman*, November, 1897, any fact which, in the sound discretion of the court, is pertinent to the inquiry, whether testified to by anyone or not, may be assumed in a hypothetic question with the view of testing the skill, learning or accuracy of the expert, or to ascertain the reasonableness or expose the unreasonableness of his opinion. A question, though it goes beyond the scope of the evidence, may be propounded upon cross-examination if its office and purpose are to elicit the reason upon which the expert based an opinion expressed by him in his examination in chief, or to ascertain the extent of his learning and knowledge of the particular subject upon which he assumes to be an expert.

Violent Deaths Among the Employees of Railroads.—On the average about six thousand persons are killed on the railways of this country every year, and upward of thirty thousand injured. Hundreds of employees are killed and thousands injured every year while engaged in coupling or uncoupling freight cars. The law of 1893 demanded that the roads should equip their cars with automatic couplers and air brakes. After all these years much more than half the freight cars remain without even automatic couplers and fewer still are fitted with the brake. Request has been made by certain railroad magnates of the Interstate Commerce Commission, that the time within which the roads must comply with the law be extended for five years. This looks like asking permission to kill or maim a hundred thousand persons in order that derelict roads may wear out their old equipment without the expense of fitting it with the required safety appliances. —*New York Herald*.

Nutrose. Nutrose is prepared from the casein of milk combined with sodium, and so converted into a soluble condition. It is a highly concentrated albuminoid food, and is represented to be free from the disadvantages of other "meat substitutes." Its advantages over meat derivatives are thus tersely summarized: 1, its high percentage (90 per cent.) of chemically pure albumin; 2, its almost complete lack of odor and taste; 3, its complete solubility in water, milk and other menstria; 4, its miscibility with ordinary food stuffs; 5, its neutralizing power as against gastric hyperacidity; 6, its easy and almost complete absorbability by the digestive organs; 7, its lack of irritant effect upon the intestinal tract; 8, its practically sterile and undecomposable condition; 9, its inexpensiveness. As to the nutrient value of nutrose, the exact assimilation experiments of Salkowski, Marcuse, Stuve and Bornstein conclusively show that the absorption and utilization of this preparation is very complete and that the albumin of ordinary food may, when necessary, be wholly or partially replaced therewith without producing repugnance, gastro-intestinal irritation or putrefactive diarrhea.—*American Therapist*.

Liverpool Supplies the Antitoxin for Diphtheria free to the Poor. A circular has been sent to the local practitioners from the medical officer of health of Liverpool intimating that a supply of antitoxin for the treatment of diphtheria has been provided by the Hospitals Committee at each of the five city hospitals, which can be obtained on application to the resident medical officer or matron at one or other of the said hospitals. The object which the hospitals committee has in view is primarily to supply antitoxin for use among the poorer class of patients;

and under any circumstances the committee will be obliged if a return showing the progress of the case be made upon a form which will be supplied at the respective hospitals. This is a step in the right direction and indicates the desire of the municipal authorities to afford every facility for the reduction of infectious diseases and for placing all classes of the community under the most favorable conditions toward recovery.

Prizes Offered by the Académie de Médecine of Paris.—Over \$8,000 were distributed in the prizes of 1897, twenty-seven in all. Only seven were awarded entire to one person; the rest were divided among the two to five who came nearest to fulfilling the terms of the award. No communications were received in competition for the Monbigne prize of 1,500 francs (scientific mission). Two prizes were not awarded, the Audiffred and Pourat (tuberculosis and intra-vascular tension). The list of recipients includes only one foreigner Stadfeldt of Copenhagen, (ophthalmology). The prizes offered for 1898 are as follows, omitting three which are only open to French writers. Académie: Infectious myelitis from the clinic and experimental point of view, 1,000 francs, annual. Alvarenga: For best work on any branch of medicine, 800 francs, annual. Aubert: For clinic and experimental research on the question whether there are any human constitutions refractory to tuberculosis, 500 francs. Audiffred: For a sovereign curative or preventive remedy for tuberculosis, discovered in twenty five years from 1896, title to an annuity of 24,000 francs. Baillarger: For the best work on the therapeutics of mental diseases, accompanied by a study of the organization of public and private asylums; 2,000 francs, biennial. Barbier: For a means of curing the diseases now considered incurable, cancer, epilepsy, scrofula, typhus, cholera morbus, etc. This prize can be distributed among those who come nearest to the aim proposed: 200 francs, annual. Bouillard: For the best work and the best curative results attained in mental affections; 1,200 francs, biennial. Bourceret: Circulation of the blood; 1,200 francs, annual. Buisson: For a cure for the diseases now considered incurable; 10,500 francs, triennial. Capuron: Experimental research in obstetrics; 1,400 francs annual. Chevillon: For best work on the treatment of cancerous affections; 1,500 francs, annual. Civrieux: Obsessions in mental pathology; 1,000 francs, annual. Clarens: Hygiene; 400 francs, annual. Daudet: Sarcoma; 1,000 francs, annual. Desportes: Practical medical therapeutics; 1,300 francs, annual. Falret: Somnambulists; 900 francs, biennial. Godard: Internal pathology; 100 francs, annual. Herpin: Abortive treatment of blennorrhagia; 1,200 francs, quadrennial. T. Herpin: Best work on epilepsy and nervous diseases; 3,000 francs, annual. Laborie: For the work that has advanced most notably the science of surgery; 5,000 francs, annual. Laennec: Infantile capillary bronchitis; 500 francs. Larrey: Medical statistics; 500 francs, annual. Louis: Sero-therapeutics, 4,000 francs, triennial. Mège: Hay fever, 900 francs, triennial. Meyrot: Diseases of the ear; 2,600 francs, annual. Monbigne: Scientific missions, medical, surgical or veterinary; 3,000 francs. Nativelle: Extraction of the active principle of some medicamentous substance, hitherto isolated; 300 francs, annual. Nivet: Sanitation of barracks, hospitals, schools, crèches, asylums, etc.; 3,000 francs. Orfila: Cocculus indicus and picrotoxina, therapeutics and toxicology; 2,000 francs, biennial. Portal: Lesions of the nerve centers and kidneys caused by the toxins of tetanus and diphtheria; 600 francs, annual. Pourat: Circulation of blood in the lungs; 1,000 francs, annual. Saint Lager: For the production of the thyroid tumor in animals by administering substances taken from the waters or soil of localities where goiter is endemic; 1,500 francs. Saintour. For the best work on any branch of medicine; 4,400 francs, biennial. Stanski: Awarded to the person who has demonstrated the existence or non-existence of miasmatic contagion, by infection or contagion from a distance. If no communications are received conforming to these requirements, the prize will be awarded for the best elucidation of any question relating to contagion in the contagious, inoculable affections; 1,800 francs, biennial. Tremblay: For the best work on the affections of the urinary passages, catarrh of the bladder, prostatic lesions, etc.; 7,200 francs, quinquennial. Vernois: Hygiene; 700 francs, annual. The prizes offered for 1899, include, besides the unchanging annuals already mentioned Académie: Physiology and pathology of

the thyroid gland; 1,000 francs, annual. Amussat: For the best work of research, both anatomic and experimental, which has realized the most important progress in surgical therapeutics; 1,000 francs, triennial. Argenteuil: For the most important improvement in the curative treatment of strictures of the urethra, or for the best work on any affection of the urinary passages; 6,800 francs, sexennial. Civrieux: Nervousness; 800 francs, annual. Daudet: Lymphadenoma; 1,000 francs, annual. Lefèvre: Melancholia; 1,800 francs, triennial. Portal: Experimental study of the inoculation and contagion of cancer; 600 francs, annual. Pourat: Experimental research to elucidate the question of the immediate and remote destination of the albuminoid aliments; 700 francs, annual. Ricord: For the best work that has appeared in the two years on the venereal diseases; 600 francs, biennial. The prizes for 1900 include: Académie: Medication by organic juices; 1,000 francs, annual. Capuron: Hydromineral treatment of albuminuria; 1,000 francs, annual. Civrieux: Delirium in general paralysis; 800 francs, annual. Daudet: Results of surgical treatment of cancer of the ovaries; 1,000 francs, annual. Falret: Clinic forms of neurasthenia and their treatment; 700 francs, biennial. Itard: For the best book on practical medicine or applied therapeutics, published at least two years; 2,400 francs, triennial. Perron: For the author of the work that has best promoted the progress of medicine; 3,800 francs, quinquennial. Pourat: Intravascular sanguine tension; 700 francs, annual. Articles must all be received by the end of February, and be written in French or Latin, with the name in a sealed envelope unless in pamphlet or book form. The manuscripts, etc., are not returned to the authors.

Hospitals.

THE new Lakeside Hospital, Cleveland, Ohio, was dedicated January 12.—The Presbyterian Hospital, Chicago, receives \$8,801 from a benefit concert given in the Auditorium January 17.

YALE MEDICAL SCHOOL is the recipient of \$1,000, the gift of Mrs. D. C. Leavenworth of New Haven, Conn., as a memorial to the late Dr. D. C. Leavenworth, a graduate of the school in 1865.

Societies.

THE HARLEM MEDICAL ASSOCIATION held its annual dinner at the local Casino, January 15. Nearly sixty were present besides Surgeon-General Sternberg, who spoke highly of the AMERICAN MEDICAL ASSOCIATION and of the JOURNAL. He advocated a greater harmony among the profession at large, of which he was pleased to report many cheerful signs. Dr. Arthur M. Jacobus represented the Medical Society of the State of New York. He referred in response to the toast to many grievances of the profession which legislation might remedy, such as Health Board encroachments upon time-honored privileges and occasional assumptions of superior intelligence. He spoke at length upon the evils of unlicensed and ignorant midwifery. Dr. Joseph E. Janvrin, as President of the New York County Medical Association referred to the character of its work and the value of its contributions to the general stock of medical progress. Dr. Thomas H. Manley, in the course of his remarks upon the entertaining Association, humorously described his early experiences of the suburb and could not but be astounded at its growth. He also hoped that trivial differences might be adjusted in the profession and that harmony would be the rule. Being an optimist he could not be otherwise than cheerful. Owing to the absence of two advertised speakers, since reported as "unavoidably detained," Dr. John Shady was forced to make an unprepared speech, which consumed several minutes. After this the meeting adjourned with cheers for Dr. Sternberg, who had sacrificed his convenience for this special occasion.

Washington.

REPORT OF THE HEALTH OFFICER.—The report of Health Officer Woodward for the week ended January 15 shows the total number of deaths to have been 96, of which number 57 were white and 39 colored. The principal causes of death: nervous disease 18, respiratory diseases 35, heart disease 6. There are at present 62 cases of diphtheria and 57 cases of scarlet fever under treatment.

COMMITTEE ON PUBLIC HEALTH.—The Committee on Public Health of the Washington Board of Trade, at its recent meeting decided to recommend to Congress the reclamation of the Anacostia Flats. The insanitary condition of these flats is largely responsible for the paludal fevers which prevail in Washington throughout the year and makes the city world-renowned for ill-health. The medical members of the committee are Surgeon-General George M. Sternberg, W. W. Johnston, G. L. Magruder, H. L. E. Johnson, L. W. Ritchie, W. P. C. Hazen, J. B. G. Cnstis, John E. Jones and George Henderson. Dr. S. C. Busey, who was chairman of the committee for several years, recently tendered his resignation.

MEDICAL AND SURGICAL SOCIETY.—At the meeting of the Society recently held Dr. Elmer Sotherton presented a specimen of ruptured tubal abscess with the history of the case. The subject was discussed by Drs. Joseph Taber Johnson and W. P. Carr. He also read a paper entitled "Hour-glass Contraction of the Uterus," which was discussed by Drs. Moran, Carr, Bowed, Morgan and J. T. Johnson. Dr. Stone read a paper entitled "The Mind Cure," which was discussed by Drs. Chamberlain, Capeheart, French, Kober and W. P. Carr.

MEDICAL SOCIETY.—At the meeting of the Medical Society on January 19 Dr. Stiles read a very instructive paper entitled "The Inspection of Meats for Animal Parasites," and Dr. Hasbrouck reported a case of hypertrophic pulmonary osteo-arthritis with photographs and specimens.

Louisville.

LEGISLATION.—Public health is being looked after by the present legislature, as several bills have been introduced in the past week which are looking to that end. Bill No. 93, introduced by Mr. Decha of Harrison County, has as its object the keeping of itinerant dentists out of the State by requiring that dentists shall have a license from the Board of Examiners, appointed by the Kentucky State Dental Association. This bill was referred to the Committee on Public Health. Bill No. 113 was introduced by Mr. Chinn of Mercer County. It authorizes the appointment of a pure food commissioner, who shall see that all mixed and adulterated food and liquors, of every character and form, are labeled, showing the ingredients. It prohibits the manufacture of both pure and adulterated goods by the same person. The leading members say that the bill can never pass, as it conflicts with too many interests and would drive many grocers out of business. It will probably not get out of the Committee on Judiciary, to which it was referred. Bill No. 39, introduced in the Senate, is similar to the one just referred to, though not so comprehensive or far-reaching. This bill was introduced by Mr. Smith of Henry County. It requires that all handlers of mixed flour shall label or brand each package of flour with the ingredients contained therein. Bill No. 40, introduced by Senator Edmonson, requires factories to print on each label the year the fruit was put up and, where it is imported in bulk, the importer must stamp on each package the date of its arrival in the State. One bill has been reported favorably by the committee which raises the age of consent of females from 13 to 16 years, and the Committee on Public Health reported favorably on the bill to prevent the sale of meat of animals dying otherwise than by slaughter. It is believed both will pass.

ASYLUM APPOINTMENTS.—The Senate Committee on Charitable Institutions refused to confirm the appointment of the colored physician, Dr. B. F. Porter, who has been appointed by Governor Bradley as third assistant physician at Lakeland Asylum for the Insane. The Senate however refused to concur in the committee's recommendation and confirmed Dr. Porter's appointment, as it was shown that he would have charge of the colored inmates only. Dr. Louise Bergmann of Louisville, who has been serving as a resident physician at the Woman's Hospital at Philadelphia, has been notified by telegram to proceed at once to Lexington to assume her duties as

third assistant physician to which position she has just been appointed by the Governor. This position was made vacant by the promotion of Dr. John L. Long, to be Superintendent of the Feeble Minded Institute, and the advancement of the assistants in consequence of his resignation as first assistant. There is some talk that the appointment of Dr. E. M. Wiley as Superintendent of the Lexington Insane Asylum, which was made during the interim of the legislature, would fail of confirmation because the Doctor is a "sound money democrat," and the legislature is largely "free silver." It is to be hoped that this will not be done as Dr. Wiley has made a most excellent superintendent.

PRISON.—The Sinking Fund Commissioners have decided to remove the male guards from the female wards of the Frankfort penitentiary, and to appoint in their place two women for that purpose.

MILK.—Health Officer Allen has introduced the policy of compelling all dairymen, whether residents of the city or county, or outside of the State, to take out a license as compelled by law, as it has been ascertained that the present law was sufficiently comprehensive to include out of town dealers who send milk to the city. It has already been the cause of an improvement in the character of milk supplied. In the Senate, Mr. Nazier of Shelby County, introduced Bill No. 45, relating to the sale of dairy products, and imitations thereof. It provides for the appointment of a milk inspector in every county, and for the stamping on all cans, boxes or packages the fact that any dairy product is adulterated.

Detroit.

AT A REGULAR MEETING of the Wayne County Medical Society December 23, Dr. Fritz Maass read a paper entitled "Toxin and Serum Treatment of Inoperable Tumors." After giving a history of the use and preparation of the serum as devised by Coley, the author presented statistics of cases treated by this method by Coley, Emmerich, Scholl and others, showing somewhat unsatisfactory results except in a small percentage of cases. The Doctor then gave a full history of a case of melanotic sarcoma occurring in his own practice treated by Coley's method. The treatment proved entirely unsuccessful. Not only that, but the Doctor considered that the treatment favored the development of metastases.

AT A MEETING of the Detroit Medical and Library Association January 10, Dr. C. W. Hitchcock read a paper entitled "Hemorrhagic Pancreatitis; a Case Having Unusual Medico-Legal Relations." The author described the disease as being one of insidious onset, but one which presents a very striking clinical picture, with its sudden, sharp and severe pain, the vomiting, collapse and evidence of profound shock. Its course has been as short as one-half hour (that is, after first known symptoms) and as long as several days. The etiology is obscure. Alcoholic excesses, previous attacks of gastroduodenitis and possibly injury are thought to be factors. Antemortem diagnosis is infrequent, though a few cases are reported. The diagnosis frequently falls on intestinal perforation, appendicitis, irritant poison or acute intestinal obstruction. Medico-legal phases are rare. Poison was suspected in one case. References to injury as a cause are few and not satisfactory. Fitz reports a case in which injury is assigned as probable cause. In the case here reported the patient told none of his physicians of any injury and denied it to one, but after his death a fellow employe alleged a fall and claim was made for insurance, the patient having held an accident policy. Antopsy established clearly the existence of hemorrhagic pancreatitis with all the usual pathologic evidences. Yet in the face of all this at least two physicians leaned to the theory of death from hemorrhage from rupture, although no such rupture could be found. The man died fifty-four hours after the first symptoms, presenting the typical clinical picture of hemorrhagic pancreatitis. Though the history of injury was doubtful and all the clinical

evidence was against its being the cause of death, yet, owing to its allegation by the only eye-witness, the differing opinion of physicians and the additional doubt as to whether or not injury might stand in a causal relation to hemorrhagic pancreatitis, a compromise of the case was advised and secured.

HARPER HOSPITAL MEDICAL BOARD.—At a meeting of the Board of Trustees of Harper Hospital held on Tuesday evening, January 11, the following staff was elected for the year 1898: J. H. Carstens, M.D., chief of staff; consulting surgeons, Theo. A. McGraw, E. T. Tappey; attending surgeons, Daniel Laferte, H. O. Walker, J. K. Gailey; junior attending surgeons, Angus McLean, P. M. Hickey, Benjamin P. Brodie, F. B. Tibbals; consulting physicians, Charles Douglass, J. J. Mulheron; attending physicians, George Duffield, W. R. Chittick, C. G. Jennings, F. W. Mann; Junior attending physicians, F. W. Robbins, B. R. Shurly; consulting oculists, L. Connor, George E. Frothingham; attending oculists, George E. Frothingham, Jr., Don M. Campbell; consulting neurologist, David Inglis; attending neurologists, J. E. Emerson, C. W. Hitchcock; dermatologist, A. E. Carrier; laryngologist, E. L. Shurly; consulting gynecologist, Helen F. Warner; attending gynecologists, H. W. Longyear, W. P. Manton, Harriet A. Gerry, J. H. Carstens; microscopist, E. H. Sargent; assistant microscopist, Thaddeus Walker; pathologist and curator, E. H. Troy.

Denver.

BUREAU OF HEALTH.—The water-supply of the city has occupied the attention of Health Commissioner Dr. Wm. P. Mun for the last three years. The lingering cases of sporadic typhoid fever stand out in bold relief when examined in the light of the general low mortality, 10.48 per 1,000 per annum, and according to the investigation of the department, the water supply is one, if not the sole, source of the infection. The annual reports for 1895 and 1896 contain graphic descriptions of the contaminated sources whence the water is supplied and attempts made by the commissioner to induce the Denver Union Water Company to act on the recommendations made by the bureau. But the company turned a deaf ear and went on disseminating filth and disease. Happily for the city the mayor, the members of the city council and the citizens of Denver are in sympathy with their energetic and fearless health commissioner. Suit was begun by the city against the company and the stockholders begin to see that the long suffering public is alive to the interests and mean business. The company made haste to introduce some of the suggestions made by the health department in order to blind the public, but the commissioner kept his eyes open and induced the members of the council to go in a body and see everything there is to be seen. The company has requested the privilege of sending their engineer and secretary along with the expedition, which request was granted. After a thorough inspection of the sources of the water supply, their filthy surroundings and inadequate filtration, there remained no more doubt in the minds of the city fathers, and to a certain extent in the minds of the officials of the company as to the correctness of the statement of the last annual report, which reads: 1. That the Mississippi Street horizontal wells and the Harrimon Ditch were subject to sewage pollution of the most serious nature. 2. That the mixed water supplied to the city furnished evidence of that pollution in the presence of bacteria to the number of as high as 5,000 c.c. during the summer. 3. That decreased use of the water was coincident with decreased bacterial contamination of the mixed supply. 4. That the typhoid fever prevalence followed the period of maximum use of the polluted water and the diminished use of polluted water seems so far to have been followed by diminished typhoid prevalence.

THE ANNUAL MEETING OF THE DENVER AND ARAPAHOE MEDICAL SOCIETY was held December 11. The event of the evening was a paper read by Dr. Sewall on the "Reduplication of the Heart Sounds and Its Clinical Signification." When he announced that the reduplication of the second sound is a perfectly normal phenomenon, and can be discerned in every man,

sound or sick, the members manifested a great deal of surprise. Dr. Sewall spoke of the causes of heart sounds and the elements which produce them. Each side has three elements and therefore six separate sounds could be heard. The reduplications are: Prolongation, splitting and doubling. The reduplication may be real or simulated. The reduplication of the second sound is heard plainest at the base of the heart, and is most marked at the end of respiration. The explanation of the cause of the normal phenomenon of the reproduction is a very ingenious one. It depends upon the non-synchronous closure of the sigmoid due to unequal arterial pressure, and as the difference in pressure is greatest at the end of inspiration the reduplication is in consequence most marked at that time. The lessening of reduplication of the second sound, the author avers, is rather a pathologic symptom. Dr. J. N. Hall, in discussing the paper, called attention to the fact that in mitral stenosis the reduplication of the second sound is pathognomonic, notwithstanding Strümpell and others to the contrary. Dr. H. B. Whitney said: "If any one would have told me a week ago that the second sound is as a rule reduplicated, and that I have been during these long years of practice like the wicked 'who hath ears and heareth not,' I would have scorned such an assumption. But thanks to Dr. Sewall, who has given me the opportunity to examine twenty patients under his tutelage, I can say that the reduplication of the second sound was a perfect revelation to me." He has heard the reduplication in fifteen cases out of the twenty. It requires, however, a highly trained ear. The election of officers resulted as follows: E. P. Hershey, president; H. B. Whitney, vice-president; J. M. Blaine, financial secretary; J. E. Rothwell, treasurer, and George Tyler, secretary. From the exhaustive report of the retiring secretary, Dr. Spivak, we glean that fourteen meetings were held during 1897; the average attendance was thirty-six; twenty-seven papers were read and eleven cases reported. The Society has 150 members. The secretary suggested that a historic sketch of the Society, which is now in its twenty-seventh year of its existence, as well as the annual Transactions, be published. The suggestions were referred to the incoming Board of Censors, which is composed of Drs. Fleming, Eskridge, Hopkins, McLauthin and Van Zant.

THE DENVER CLINICAL SOCIETY.—Notwithstanding the fact that our sister-practitioners avail themselves of all the privileges which the existing medical societies afford, and not only do they grace the meetings with their presence, but also take active part in presenting and discussing papers in a manner by no means less dignified and scholarly than their brother practitioners, yet they have an organization of their own called by the above name. At the suggestion of Dr. Mary B. Bates, the women physicians have organized the society, which is in its third year of existence, and has for its object "the mutual improvement arising from informal discussion of interesting cases and new methods of treatment, as well as to foster greater sociability, closer acquaintance and sympathy among the members." The Society has twenty members and meetings are held bi-monthly. The present officers are: M. Jean Gale, president; Una Roberts, first vice-president; Catherine Hayden, second vice-president, and Josephine L. Peavey, secretary and treasurer. At the last meeting, held January 4, Dr. Lavney read a paper on "Uremia," with reports of a case of uremic convulsions, which necessitated emptying of the uterus. The patient recovered. The paper was discussed by Drs. Gale, Yont and Roberts.

Philadelphia.

EPIDEMIC OF TYPHOID FEVER.—The city authorities have recently had the most convincing kind of an object lesson afforded them regarding the direct relation of cause and effect existing between a sewage-polluted water-supply and the prevalence of typhoid fever in a thickly settled community. Some years ago their attention having been directed to the greater proportionate number of deaths from this disease in Philadelphia than in other large cities, and the cause being indicated and recognized as sewage pollution of the water-supply, provision was made to prevent such contamination by the construction of a large intercepting sewer, which runs nearly parallel with the Schuylkill River and empties its contents below the city

water works. Since its completion there has been observed a decided diminution in the number of cases of typhoid fever until recently. On November 16 last some workmen in flushing this great sewer turned on too great a head of water and the sewage backed up and before it was stopped overflowed for a few hours only into the Schuylkill. The polluted water was pumped principally into the Queen Lane Reservoir, supplying eight wards, which are considered as being among the healthiest wards of the city under ordinary circumstances. The first results were shown in the sudden increase of typhoid in these wards. Later there was a decided rise in the number of cases in other portions of the city. The reports of the health office as published weekly show that for the week ending November 22 there were only 34 cases, November 29, 54; December 6, 117; December 13, 125; December 20, 110; December 27, 107; January 3, 97; January 10, 165; January 17, 201; January 24, 212. The health authorities of the city have done their duty promptly. Dr. Abbott, head of the bacteriologic department, has prepared a report containing a striking array of figures and water analyses, accompanied by a chart or diagram of the affected districts. The County Medical Society has adopted resolutions condemning the water supply and calling for the construction of a filtering plant as the only remedy. The suggestion was made by a member of Councils to ask the assistance of the United States Marine-Hospital Service, which, however, met with little favor. In view of the fact that by a popular vote on a new loan bill, Councils were authorized to spend more than a million of dollars in the specific purpose of improvement of the water supply, it would seem that the situation has been well summed up by the mayor of the city, Mr. Warwick, who said in an interview: "There is only one thing that can be done now and that is to pass the loan bill. The betterment of the water supply is the crying need of the people and this administration will attend to it just as soon as the money is available to accomplish the purpose." Dr. Benjamin Lee, Secretary of the State Board of Health, improves the occasion to point out the fact that for the last ten years the board has been endeavoring to secure the passage of a law to protect the Schuylkill as well as other rivers in Pennsylvania which supply cities with water from being the repositories of drainage, but without success. He ascribes the present outbreak directly to the pumping of polluted water into the Queen Lane Reservoir, and believes that it could have been averted by a proper system of filtration, such as had been advised by the City and State Boards of Health years ago. There can be no question but that the present outbreak has occurred at a most opportune time to strengthen the arguments of our health authorities and to enlist public opinion in favor of a much needed public improvement which Councils will probably be compelled to carry out.

PHYSICIANS' BENEFIT ORGANIZATION.—The Mutual Aid Association of the Philadelphia County Medical Association was the subject of the meeting of the County Society January 26. Addresses were made by Dr. Edward Jackson, president of the Society; Dr. Chas. Herman Thomas, president of the Mutual Aid Association, and John B. Roberts, ex-president. Dr. A. F. Currier of New York read a communication entitled "The Fifty five Years of the New York Society for the Relief of Widows and Orphans of Medical Men." Dr. Chas. H. Leale, president of the New York Society, was also present and addressed the meeting. The Rev. Dr. Krauskopf, by invitation, spoke on "The Necessities of the Widow and Orphan," and the Rev. Chas. Wood spoke on the subject of "Charity." The meeting was largely attended and a number of visitors interested in philanthropic work were present. A reception and collation at the University Club followed the exercises, Dr. M. O'Hara was chairman of the committee having the entertainment in charge.

THE ANNUAL MEETING of the Faculty of the Philadelphia Polyclinic and College for Graduates in Medicine, was held January 17. The report of the Secretary showed that the number of pupil-physicians in attendance was larger than ever before in the history of the College. The most popular ticket was that for the general course. Of the special tickets taken, those in ophthalmology exceeded those of any other branch. The report of the Treasurer was equally satisfactory. In addition

to the payment of all fixed charges of maintenance, the Faculty had contributed \$1,800 to the sinking fund. This fund was established for the purpose of gradually wiping out the mortgages on the buildings, freeing the institution from debt and putting it on a sound financial basis that shall be independent of the number of students and of other circumstances. The officers that have served for 1897 were re-elected: Howard F. Hansell, president; Lewis Steinbach, vice-president; Max Stern, Secretary.

AT THE JANUARY MEETING of the Ophthalmic Section of the College of Physicians, held on the 19th inst., after transaction of the scientific business, the election of officers for 1898 resulted in the choice of Geo. C. Harlan for chairman and Howard F. Hansell for clerk of the Section for the ensuing year.

CHANGE OF ADDRESS.

Bausch & Lomb, from Masonic Temple to Stewart Building, Chicago.
Chancellor, C. G., from 613 Pine to Oriol Building, St. Louis, Mo.; Cunningham, S., from Taylor to Dallas, Texas; Cresswell, G. W., from 8 De Kalb St. to 36 Spruce St., Chicago, Ill.
Drake, G. W., from Nashville, Tenn. to Hollins, Va.
Houghton, E. F., from Rochester to Tilton, N. H.; Hawley, E. A., from 477 E. 45th to 663 Congress St., Chicago, Ill.
McLaughlin, from Austin to "Tower House" Galveston, Texas; McBride, M. A., from Yorktown to Sidney, Texas; Marcussen, W. B., from Harrison and Center Ave to 571 W. Madison St., Chicago, Ill.
Trumbower, M. R., from Denver, Colo. to Monett, Mo.
Uhler, J. R., from 661 W. Fayette St. to 1531 McCulloch, Baltimore, Md.
Whiting, E. D., from Chicago, Ill. to Alma Sanitarium, Alma, Mich.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from January 8 to 14, 1898.

Capt. Charles F. Mason, Asst. Surgeon (U. S. Military Academy, West Point, N. Y.), is granted leave of absence for two months, with permission to go beyond sea, to take effect April 1, 1898.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending January 22, 1898.

Surgeon A. G. Cabell, ordered home and granted three months' sick leave.

P. A. Surgeon A. W. Dunbar, order of January 12 modified; detached from the "Nashville" and ordered to the "San Francisco," by steamer of January 22.

OBJECTIONS TO THE ANTIVIVISECTION BILL NOW BEFORE THE SENATE OF THE UNITED STATES.

BY WILLIAM H. WELCH, M.D.

JOHNS HOPKINS UNIVERSITY,
BALTIMORE, MD.

The following statement has been prepared by the writer in order to meet the requests of several Senators of the United States and of physicians for objections to Senate bill 1063, which has been reported unanimously by the Committee on the District of Columbia. It is believed that many have been misled by efforts of advocates of the proposed legislation to make it appear that the bill is intended only to check alleged abuses of animal experimentation and not to interfere with its proper uses. A main purpose of this statement is to show the error of this assumption.¹ Much of the same ground has already been covered by others in various protests and publications.

The provisions of Senate Bill 1063 are so complicated and in several instances doubtful in their interpretation, and the objections to the bill are so numerous and their full presentation would require so much space, that only some of the principal arguments against it can be considered within the compass of this succinct statement.

1. The bill is entitled "A Bill for the further prevention of cruelty to animals in the District of Columbia." This title is misleading, as it does not indicate that the bill is intended solely for the restriction and regulation of experiments upon animals. The recommendation of the Commissioners of the District of Columbia in their report upon a bill of the same title and of similar contents in the 54th Congress (S. 1552) that the title be changed to read "A Bill to regulate vivisection in the District of Columbia" was not adopted. It may well be questioned whether some who have signed petitions in favor of the bill have

¹ As a matter of fact no abuse of vivisection such as would justify any restrictive law whatever has been demonstrated in this country. The experience in England has shown the folly of the belief of some men of science and physicians that any compromise in this matter with antivivisectionists will check in the least their agitation of the subject. Upon this point I will quote, by permission, a few sentences from a private letter written by Michael Foster, who is recognized in this country as well as in Great Britain as the leader in his department of medical science. The letter was written to a prominent physiologist in this country: "I have always said and always shall say that the necessity of a restrictive law has never been shown. The English Commission failed to demonstrate any abuse such as could justify the measures adopted; and from what I know of America and Americans I am confident no such laws are needed with you. Indeed, my objections to the Act as a politician are quite as strong as my objections as a physiologist; the Act is stamped with that mark of bad statesmanship, *middlemoresness*."

If the time were to come over again, I should fight tooth and nail against any act at all, on the ground that all such legislative restrictions are unnecessary, that instances of cruelty, that is of heedless causing of pain on the part of physiologists are, to say the least, rare, and that public opinion aided by the ordinary law is quite sufficient to cope with such cases. (I of course assume that vivisection is absolutely necessary for the progress of physiology.) And, much as I hate public agitation, I should throw myself into agitating against such measures, sacrificing my little portion of present science for the sake of science to come. My advice to you is, accept no compromise whatever, refuse to admit for a moment the need of such a law, and fight against it everywhere, in the newspapers and on the platform, and if the situation demands it, even imitate your opponents and refuse a political vote to a candidate who will not pledge himself to vote against it. I do not think I can say anything stronger than this last. To repeal a law is a very different thing from opposing the making of one."

not been misled by the title as to the real contents of the bill.

2. The authorship of this bill is claimed by the antivivisection committee of the Washington Humane Society (annual report, 1895, p. 24). The attitude of this society toward experimentation upon animals is apparent in the report of its president for the year 1894, where he said: "The subject of vivisection (experiments upon animals) has been frequently before your executive committee during the past year, and but one sentiment has been expressed, viz., that of utter abhorrence and condemnation of the inhuman practice which, according to the oft expressed opinion of the best physicians and surgeons, is of no practical value to science or medicine." It should be borne in mind that this bill emanates wholly from those hostile to animal experimentation and who, as appears from the foregoing quotation, do not hesitate to misstate the opinion of the great body of the medical profession as to the value of animal experiments. No one familiar with the needs of scientific and practical medicine and of biological science and possessing skilled knowledge upon the subjects which the bill proposes to regulate has been consulted or had any hand in the drafting of the bill.

3. Medical and scientific men have never had adequate opportunity to present the arguments against this bill before the Committee on the District of Columbia, which has reported favorably upon it. At the hearing of a similar bill before this Committee on April 17, 1896, Surgeon-General Sternberg said, "We did not know of this hearing until today, and were compelled to come here without any previous preparation." Surely a bill which is of far more than local interest, as appears from the numerous communications regarding it from all parts of the country, and which in its direct and remote bearings, in the opinion of enlightened physicians and scientists, vitally concerns the future progress of medicine and biological science in this country, never should have been reported by the Committee without thorough investigation as to its necessity and its effects and without full opportunity, granted not only to physicians of the District of Columbia but to others, to prepare and submit arguments against it. An hour's time granted to a few hastily summoned physicians and scientific men of the District, who came without preparation, did not afford the requisite opportunity to present adequately the objections to the bill.

4. Any one who is at all familiar with the writings and the propaganda of the antivivisectionists knows that their ultimate aim is to abolish animal experimentation altogether. They demand only such measure of restrictive legislation in the present bill as they think they may be able to secure at the present time. Concession to these demands will not check their agitation of the subject and their efforts to secure more stringent laws, as has been abundantly

demonstrated in England, where some medical and scientific men unwisely thought that by yielding to relatively moderate demands for legislation, further agitation of the subject would end. On the contrary, bills for the total abolition of experiments upon animals have been introduced into the British parliament since the passage of a bill similar to Senate Bill 1063.

5. Although it is contended by advocates of the bill that it will not interfere with the proper uses of animal experimentation, it is to be noted that the remarks of these advocates at the hearing before the Committee and the favorable report of Senator Gallinger are occupied largely with the presentation of the stock arguments of antivivisectionists against the value and the justification of experimentation upon animals. The most important of these arguments are the following: *a.* That medical and scientific men are divided in opinion upon this subject; *b.* that experiments upon animals have yielded results of little or no value to medicine or science; *c.* that such experiments are conducted with wanton cruelty and are brutalizing to those who witness or practice them. These arguments have been refuted many times. It would require a voluminous treatise to present the evidence relating to them adequately. It must suffice to mention only a few points.

a. It is untrue that there is any material division of opinion among well informed medical or scientific men as to the necessity and value of animal experiments. The names of a very few more or less prominent physicians, in no instance themselves scientific experimenters, are constantly cited, in some cases incorrectly or incompletely, by antivivisectionists in support of their position. Lists of other physicians collected by antivivisectionists as opponents of animal experimentation will not in general bear scrutiny as to the professional standing or scientific attainments of the majority of those whose names are given. The incorrectness of the statement of antivivisectionists here challenged must be apparent from the fact that whereas not a single medical or scientific society is known to have favored this bill, over a hundred such societies, which assuredly represent the great body of physicians and scientists of this country have protested against its passage. These societies represent the rank and file of the medical profession and not exclusively "ultra-scientists," as has been claimed. It is therefore unhesitatingly asserted that the medical profession and scientists, so far as their opinion receives authoritative utterance, are overwhelmingly opposed to this bill.

b. The constantly reiterated statement of antivivisectionists that animal experimentation has been of little or no value to medicine can be the result only of ignorance or of wilful misrepresentation. It would be surprising, indeed, if the experimental method, which is essential to every other science and has been the great instrument of modern scientific progress, should have no value for medical science. Surely this is a matter concerning which the judgment of the great body of enlightened physicians should be decisive. The progress of medicine from the time of the discovery of the circulation of the blood, which was based upon the results of animal experimentation, up to the present time, has rested in very large measure upon discoveries which could have been made only by experiments upon animals. It must suffice here to cite only a few illustrations of the practical value of animal experimentation, such as the establishment

of the germ doctrine of disease, the introduction of antiseptic surgery, the prevention of childbed fever, the antitoxin treatment of diphtheria and other diseases, the prevention of rabies by Pasteur's method of inoculation, the successful treatment of myxedema and cretinism by thyroid extracts. Countless thousands of human lives have been saved and will continue to be saved by methods of prevention and treatment of disease, which are derived from the results of animal experimentation. Recent years have been particularly fruitful in discoveries of the highest importance resulting from animal experimentation. Never was there so little justification to hamper in any way the work of those engaged in searching by experiment for means of preventing and curing disease.

c. The claim of antivivisectionists that scientific experimentation on animals brutalizes those who witness and practice it, is an insult, without shadow of foundation, to a class of scientific workers unselfishly devoted to the investigation of problems of the highest importance to the welfare of mankind.

There is no part of the campaign of the antivivisectionists conducted with such gross misrepresentation of the facts as that intended to make the public believe that scientific experiments upon animals are conducted cruelly, that is, with the infliction of needless pain. A large part of antivivisection literature consists of leaflets and broadsides distributed wholesale among the public, containing pictures of animals and descriptions of experiments, which are in general so erroneous or garbled or unintelligible to most of those who read them, that they convey utterly false impressions. It is repugnant to the spirit of medicine and of science to resort to similar methods in order to counteract the deplorable effects of these emotional and misleading appeals of antivivisectionists to the general public. The charge of any considerable abuse of the practice of animal experimentation on the ground of cruelty, especially in this country, has been abundantly refuted by articles in journals and other publications, which unfortunately rarely come to the notice of the great majority of those who receive the gruesome circulars of antivivisectionists. Whenever the conditions of the experiment permit, and this is in the great majority of painful vivisectional experiments, all trained experimenters place the animal during the operation completely under the influence of anesthetics. There is no evidence that there exists today in any properly conducted laboratory in this country any abuse of vivisection on this score.

6. The advocates of this bill have not been able to point to a single authenticated instance of the abuse of animal experimentation in the District of Columbia. The same inability to specify instances of abuse in Massachusetts was demonstrated in the recent hearing before a committee of the legislature of that State relating to a bill to control animal experimentation. Notwithstanding most violent efforts on the part of English antivivisectionists to excite popular feeling by charges of wanton cruelty against scientific experimenters upon animals, the Royal Commission appointed to inquire into the matter "entirely acquitted English physiologists of the charge of cruelty." The Committee recommending Senate Bill 1063 has attempted no similar inquiry for this country, but it can be confidently predicted that similar charges made in the most reckless and wanton manner against American physiologists would be found to be equally unfounded.

It is not true that secrecy is practiced in the conduct of such experiments. In scientific publications these experiments are described in detail. There is no effort made to prevent properly qualified medical and scientific men from witnessing these experiments. For manifest reasons it would be as improper and undesirable to throw open such experiments to the inspection of those without any training or competence to judge of their character and value, as it would be to give similar publicity to surgical operations. In the absence of any demonstration of abuse of the practice of animal experimentation in the District of Columbia, this bill is unnecessary.

7. It is well understood that the organized and strenuous efforts of antivivisectionists to secure congressional legislation upon this subject is not so much to check abuses in the District of Columbia, where in fact they do not exist, as to influence legislation in the various States of the Union. Although they have made repeated attempts to secure legislation, generally far less stringent than that contemplated in this bill, in different States, they have hitherto been unsuccessful. Wherever full and fair opportunity has been given to physicians and scientific men, they have had no difficulty in demonstrating to the satisfaction of committees of our State legislatures the objections to any such legislation. We would call particular attention to the convincing arguments urged successfully against a much milder bill recently introduced in the legislature of Massachusetts, a State in which the antivivisectionist agitation has been particularly active.

8. The experience with legislation, similar in character to this bill but surrounded with more effective safeguards against interference with scientific experimentation in England, has been most unfortunate in its influence upon the advancement of medical science in that country. Many scientific workers in England, including Lord Lister, one of the greatest benefactors of the human race through his introduction of antiseptic surgery, have preferred to leave their country and conduct their experiments in continental laboratories, rather than submit to the vexatious restrictions upon their work. Earnest appeals have been sent by eminent men of science in England to physicians in this country not to repeat their mistake of yielding to the demands of antivivisectionists in this matter.

9. The District of Columbia already has an unusually comprehensive and effective law for the prevention of cruelty to animals, and there is no need of further legislation in the direction contemplated in this bill. Only properly conducted scientific experiments under proper authority are now allowed. Those who conduct experiments upon animals are no less subject to the provisions of the existing law than other members of the community. If they can be convicted of cruelty in the practice of their experiments, the present law provides adequately for their punishment. The antivivisectionists complain that they are unable to secure convictions of experimenters upon animals under the present law. If so, it is because they can furnish no evidence of cruelty in the conduct of the experiments convincing to a court of justice. Their demand that the doors of laboratories shall be thrown wide open to agents of their societies in order to procure evidence, would lead to a system of outrageous espionage utterly foreign to our system of government, and degrading and intolerable to the scientific men in charge of the laboratories.

10. This bill is unanimously opposed by the great

scientific and medical bodies of this country, National, State and local, who recognize in its provisions a blow to freedom of investigation and to the advancement of medicine and biology. Among the five score and more societies which have protested against this bill may be mentioned The National Academy of Sciences, The American Association for the Advancement of Science, The Society for the Promotion of Agricultural Science, The AMERICAN MEDICAL ASSOCIATION, The Congress of American Physicians and Surgeons, The American Public Health Association, The United States Veterinary Medical Association, The Association of American Physicians, The American Surgical Association, The Association of American Medical Colleges, The New York State Medical Society and Association, and other State Societies, the New York Academy of Medicine, etc. The assumption that the protests of these societies have been made in ignorance of the provisions of the bill is absurd. It would be incomprehensible if Congress should ignore or disregard the united voice of these great organizations in a matter which directly concerns the welfare of medicine and biological science.

11. Although there is abundant evidence in the Report recommending this bill that the real sentiments of its advocates are hostile to scientific experiments upon animals, it is nevertheless asserted by them that the bill, if it should become law, would not in fact interfere with the proper uses of animal experimentation for scientific investigation and study. Such an assertion can be made only by those unfamiliar with the needs of medical and biological science and with the purposes of experimentation upon animals, or else ignorant of the provisions of the bill. To take up in detail all the provisions of the bill and to point out fully the manifold ways in which they would interfere with proper and legitimate uses of animal experimentation, would require more time and space than can here be given. This work has been done in part, but only in relatively small part by others, notably by the Secretary of Agriculture, the Hon. James Wilson, and by the former Acting Secretary of Agriculture, Dr. Charles W. Dabney, Jr., in their published letters addressed respectively to the Hon. Redfield Proctor and the Hon. James McMillan. It must suffice here to indicate only a few of the ways in which this bill would prove injurious to medicine and biology, but enough will be shown to demonstrate its fatally defective character.

A. The bill provides (Sec. 2, *b*,) that "The experiment must be performed by a person holding such license from the Commissioners of the District of Columbia as in this Act mentioned, or, by a duly authorized officer of the Government of the United States, or of the District of Columbia." It further provides (Sec. 3) that the Commissioners of the District may require the place in which any experiment is made by a licensee to be registered in such manner as they may direct and that every place for the performance of experiments for purposes of instruction shall be approved by the said Commissioners and registered in such manner as they may direct. It also provides (Sec. 5) "That the Commissioners of the District may direct any person performing experiments under this Act from time to time to make reports to them of the methods employed and the results of such experiments, in such form and with such details as the said Commissioners may require," and again in Sec. 7 the bill provides that "The Commissioners of the District

may at any time disallow or suspend any certificate given under this section."

It is evident that the bill gives uncontrolled discretion to the Commissioners of the District of Columbia in the granting of all licenses permitting experiments upon animals. They may if they choose, grant all applications for license or they may refuse all such applications and thereby prohibit all animal experimentation in the District, except that conducted by officers of the Government of the United States or of the District of Columbia. Experiments by the latter officers, as well as by licensees, they may hamper so as to make the privilege of experimentation practically useless, by demands for reports upon the methods and results of experiments at any stage of the experimental investigation as often and with as much detail and in such form as they choose. An unfinished experimental research can be interrupted or brought to an end at any time by suspension of the license in the discretion of the Commissioners. No provision is made for any hearing by the applicant or the licensee. There is no appeal from the decision of the Commissioners. They are the sole arbiters in the matter. They are made the dictators of the medical profession by this bill in matters requiring expert knowledge and sympathy with the needs of medical science.

No one can foretell in what manner the District Commissioners would exercise the arbitrary powers conferred upon them by this bill. It is certain that if they exercised them so as to meet the approval of those from whom this bill emanates and the antivivisectionists in general, who are its advocates, they would antagonize the medical profession and scientists and would inflict serious injury upon human and veterinary medical science and upon biology. On the other hand, if they administered the law so as to meet, so far as the bill permits, the wishes of physicians and scientific men, they would as surely antagonize the great majority of the advocates of the bill, who would continue their agitation and endeavor to secure still more prohibitory legislation.

Among the many objections to this bill there is none more fatal in the principle involved or likely to be more so in the practical working of the proposed legislation than that this bill places in the hands of a body of men, who need not be and are not likely to be physicians or men of science, arbitrary powers, requiring skilled knowledge in their use, concerning matters of the highest importance to medicine and biological science and to the welfare of mankind and of animals.

B. The bill provides (Sec. 6) "That the President of the United States shall cause all places where experiments on living vertebrate animals are carried on, in the District of Columbia, to be, from time to time, visited and inspected without previous notice for the purpose of securing compliance with the provisions of this Act; and to that end shall appoint four inspectors, who shall serve without compensation, and who shall have authority to visit and inspect the places aforesaid, and who shall report to the President of the United States from time to time the results of their observations therein, which shall be made public by him."

It will be observed that this section makes no provision that the inspectors called upon to scrutinize and report upon the experimental work of physicians and scientific men shall possess any special qualifications for such remarkable and responsible functions.

Can it be assumed that the President will appoint only those who possess the requisite qualifications and where will he find them? Our Universities and Medical Colleges and Hospitals and Government Laboratories search the country over to find men fitted to conduct the experimental investigations which this bill would regulate and control and they have difficulty in finding those with requisite training, scientific knowledge and special skill. And now this bill provides that over such men as these shall be placed inspectors to determine whether their experiments are performed in the proper manner and upon proper animals and for proper purposes and to make reports upon their experiments, which reports shall be made public.

The character of the inspection desired by the advocates of this bill is made sufficiently evident by the provision of the original bill (S. 1552) that the Commissioners of the District "shall appoint and authorize an agent of the Washington Humane Society to make such inspection." The attitude of this society toward animal experimentation is clear from the extract from one of its reports already cited (p. 285). It certainly may be reasonably assumed that this society and antivivisectionists in general will claim and will secure representation among the inspectors provided for in this bill. Nor is it unreasonable to suppose that they may even control the majority of the inspectors. In larger or smaller part, therefore, the inspection will doubtless be by men or possibly women, not only without special scientific knowledge but actually opposed to experimental medical or biological science. It would be entirely in the power of such inspectors to render the conditions for experimental work such that no one would care to undertake it.

It is a libel upon common sense to assert, as is insistently done by the advocates of this bill, that the objection of experimenters to any such system of inspection as that provided for in this act, is due to their fear of exposure of wanton cruelties practiced by them in the secrecy of the laboratories. As a matter of fact, no secrecy surrounds the practice of animal experimentation, and any properly qualified person has free access to the laboratories where such experiments are made.

C. The hardship which would be inflicted upon those engaged in experimental research by the provisions of the bill that at any stage of their investigations they may be called upon to furnish detailed reports of the methods and results of their work and that those, with probably no comprehension of the nature and purposes of the experiments, shall make reports thereupon, which shall be published, can be fully appreciated only by those who are acquainted with the conditions under which scientific inquiry is prosecuted. There are many important scientific investigations which would probably not be undertaken at all under any such vexatious conditions as these. These provisions, as well as others in the bill, can be utilized constantly to harass experimenters in case the law should be administered, as is not at all improbable, by those unfriendly to experimental inquiries in medicine and biology.

D. The bill prohibits important and necessary experiments and surrounds the performance of others with such restrictions as virtually to prohibit them. Exactly how far this prohibition extends can not be determined without an interpretation by the courts of

certain doubtful provisions of the bill, nor can any one foresee what new kinds of experiment, not now provided for in the bill, the future progress of medicine and biology will require.

The bill provides (Sec. 2, *a*) that "The experiment must be performed with a view to the advancement by new discovery of physiological knowledge, or of knowledge which will be useful for saving or prolonging life or alleviating suffering." If this provision be interpreted according to the explicit language used, and it may be presumed that the courts would so interpret it, no experiment can be made (except demonstrations for lectures provided for elsewhere in the bill) which is not for the advancement of knowledge *by new discovery*, and this knowledge must be of one of two kinds, either physiological or such as will be useful for saving or prolonging life or alleviating suffering.

The term "physiological" is used both in a broad and a narrow sense, and it can not be confidently predicted how the courts might interpret it. To compel an experimenter to pause before each experiment which he is about to make and consider whether he can demonstrate to the satisfaction of a court that the experiment, if not for the advancement of physiological knowledge, is for the advancement *by new discovery* of knowledge, which can be utilized in saving or prolonging life, or alleviating suffering, would not be conducive to progress in the very kind of knowledge specified. The history of scientific discoveries in medicine, no less than in other fields, demonstrates that experiments undertaken without any thought of practical application, and yielding results which appear at the time to be devoid of all practical utility, have often laid the foundations of knowledge of the highest importance to mankind.

Two valuable lines of experimentation at once suggest themselves as forbidden by the words of this section, viz., experiments to confirm results obtained by others, and experiments to acquire manual skill in performing surgical operations. The first of these restrictions was pointed out by Dr. Chas. W. Dabney, Jr., former Acting Secretary of Agriculture. Although the report upon the bill states that "the bill does not bear this limited construction," it is difficult to see how the plain language can be construed otherwise, and, if it was not the intention to prohibit confirmatory experiments, the question arises why those who drafted Senate Bill 1063, in copying this section from the British law, omitted the paragraph in the latter which expressly provides for experiments made "for the purpose of testing a particular former discovery alleged to have been made." Certainly the framers of the British law could not have considered that experiments confirmatory of alleged discoveries were already provided for by the section in question or they would not have added the paragraph omitted from the Senate bill. There is no other natural inference than that it was deliberately intended to forbid confirmatory experiments.

Experiments upon animals in order to acquire manual skill in performing surgical operations, certainly are not experiments for the advancement of knowledge *by new discovery*. Whether it was intended to prohibit such experiments is not clear. In Sec. 2, *c*, it reads "nor in tests of surgical procedure need animals be kept completely anesthetized during the process of recovery." There is nothing, however, here or elsewhere in the bill to indicate that these tests are

to form any exception to the general requirement that, save demonstrative experiments for lectures, all permissible experiments must be for the advancement of knowledge *by new discovery*. If, as seems to be the natural interpretation of the language of the bill, surgeons are not to be permitted to perfect themselves in methods of operating by experiments upon animals, this prohibition can be characterized as nothing less than inhuman. The only alternative is to make a human being instead of one of the lower animals the subject of experiment. There are many operations which a surgeon may wish first to try upon an animal before attempting them upon a human being. An eminent surgeon has said that a surgeon should not perform the operation for circular suture of the intestine and for intestinal anastomosis upon man without first practicing it on animals.

The bill provides (Sec. 2, *c*), that "The animal must, during the whole of the experiment, be completely under the influence of ether or chloroform," excepting in inoculation experiments, tests of drugs or medicines, and during recovery from surgical operations. It is absurd to limit the choice of anesthetics to two. There are other anesthetics which produce equal insensibility to pain, and any one at all acquainted with physiological experiments, knows that there are experiments in which it is safer, better, and sometimes for the purposes of the experiment necessary, to produce anesthesia in other ways than in the only two permitted by this bill.

The absurdity of the claim that this bill is simply restrictive and regulative, and not prohibitive of experiments upon animals, can be shown in many of its provisions, and especially by that which forbids the survival of the animal after an operation unless kept continuously under the influence of ether or chloroform. The only exceptions to this provision are inoculation experiments, tests of drugs or medicines and tests of surgical procedure. The experiments which are prohibited by this provision are so many that they can not even be enumerated within the compass of this statement. All physiological and pathological experiments where the ends of the experiment can be attained only by observation of the animal for days or weeks after some operation, or after the administration (save by inoculation) of anything except drugs or medicines which may give pain, are prohibited by this bill, for it is impracticable to keep animals during such periods of time continuously anesthetized. Such important experiments as those which have shed light upon the functions of the stomach by gastric fistula, or of the heart by the experimental production of valvular lesions, or of the central nervous system, kidneys, and indeed most of the organs of the body by observations extending over some length of time after an experiment, are all prohibited by the conditions of experimentation imposed by this bill. All experiments are prohibited in which anything, except drugs or medicines, is simply fed or introduced into the stomach in case the experiment is calculated to give pain to the animal and extends beyond the limited period in which it is practicable to keep the animal under ether or chloroform.

It may well be questioned whether it was intended to forbid the large class of important and necessary experiments of the characters described. If it was not, then the bill is so loosely drawn that it should never pass in its present form. If it was intended to exclude all of these experiments, then the blow which

its enactment would inflict upon biological and medical science is simply brutal.

There are other kinds of valuable experiments which are prohibited by this bill besides those specified, but enough has been said to show the error of the assertion made in the Report recommending it that "the bill is restrictive, not prohibitive," and to demonstrate that among the prohibited experiments are many of the highest scientific and practical value, including many which involve far less suffering to the animal than some which are permitted.

E. The bill provides (Sec. 4) "That a license shall not be granted to any person under the age of twenty-five years, unless he be a graduate from a medical college, duly authorized to practice medicine in the District of Columbia." There are graduates of Zoology and other departments of Biology under 25 years of age eminently qualified by their training for investigations involving experimentation upon animals. Concerning the effect of this provision upon the work of the Bureau of Animal Industry Dr. Dabney, in the letter already cited, says: "It would at once stop some of the experiments now in progress, and if it had been enforced in the past years would have prevented a large proportion of our scientific employes from doing this class of work."

F. The greater part of the investigations requiring animal experimentation in the District of Columbia are conducted in the Bureau of Animal Industry under the Department of Agriculture. This bill takes the scientific work of a Department of the General Government to a considerable extent out of the hands of the Secretary of Agriculture, and places it to a corresponding extent under the control of officials of the District of Columbia, and that too for matters which concern the agricultural interests of the entire country and only in relatively small measure concern the District of Columbia. The bill accomplishes this by providing that the Commissioners of the District may direct any person performing experiments to report to them from time to time the methods and results of their experiments in such form and with such detail as the Commissioner may require. It will be observed that it is not the Secretary of Agriculture who is to be called upon to report, but it is his subordinates. The bill further provides that if any of five kinds of animal (cat, dog, ass, mule, horse), are used for the experiment, a special certificate setting forth certain facts must be procured. The bill is singularly indefinite as to these certificates, especially not stating by whom they are to be given, or to whom application for them is to be made. If, as is not improbable, it was the intention that these certificates should be granted by the Commissioners, then the scientific work of the Bureau of Animal Industry is placed practically under the direction of these District officials, for no provision of the bill exempts officers of the Government from the necessity of procuring these certificates, as is the case with licenses.

No attempt has been made in this statement to present a complete analysis of Senate Bill 1063 and to point out all of its objectionable provisions or even to exhaust the objections to such as have been considered. No such complete analysis is necessary in order to prove the error of statements in the report recommending it that it is "reasonable and wise," "restrictive and not prohibitive," and permissive of all "useful investigations." It may be that the committee recom-

mending the bill believed it to possess the moderate and reasonable character claimed for it. The defects of the bill are evident enough to those who are familiar with the requirements of modern medicine, in its scientific and practical aspects, and with the needs of biological science. So evident indeed are they that it has generally seemed unnecessary to medical and scientific societies and individuals, who have protested in hundreds against the passage of the bill, to do more than emphasize on the one hand the great benefits derived from animal experimentation and on the other the restrictive and prohibitive features of the bill. Apparently so convinced have many of the advocates of the bill been of its moderation, that they have assumed that these protests have been made in ignorance of the provisions of the bill, a most unwarranted and gratuitous assumption. It is not to be expected that any considerable number of the committee to which the bill was referred should possess that technical, expert knowledge essential for an intelligent judgment as to the effects of a complicated bill which prescribes by whom, and for what purposes, and upon what animals, and in what manner, scientific experiments shall be performed.

It surely could not have been the intention of the Senate Committee recommending this bill to inflict such serious injury upon medicine and science as, in the opinion of those who by their training, occupation and special knowledge of the subject are most competent to judge of its workings, it certainly would inflict.

THE ANTITOXIN TREATMENT OF TUBERCULOSIS.

OR THE DIRECT (TUBERCULIN PREPARATIONS) VERSUS
THE INDIRECT (ANIMAL SERUM) METHOD OF IMMUNIZATION AGAINST TUBERCULOSIS.

Read before the Denver Medical Association and Arapahoe County Medical Society, Dec. 14, 1897.

BY CHARLES DENISON, A.M., M.D.
DENVER, COLO.

Since Koch's discovery of tuberculin some seven years ago, we no longer wonder that the majority of medical men were turned away from the employment of this remedy by its ill-advised use, and the resulting gross effects, as shown by Virchow, the great pathologist.

From the absurd advertisement of a Swiss barber "tuberculin injections given here," and the equally preposterous belief which at first prevailed that a means to destroy tuberculosis had been discovered, as easy of use as a household remedy, we have come to learn that if cure it will, it must be by a concentration of skilled effort, and a technique involving as much discrimination in diagnosis and care as does the differentiation of a complicated eye refraction, the microscopic determination of blood changes due to disease, the endoscopic study of internal organs, or any other delicate field of professional work.

The great mistake of the celebrated discoverer of tuberculin (which in a measure is applicable, also to his later discovery tuberculin T. R.) was that there was no due recognition of the failures of physicians in the diagnosis of tuberculosis. In other words medical men failed to recognize the great variation of the disease to be treated by so powerful a remedy. We can now see how unfortunate it was for Koch to

allow his tuberculin to be indiscriminately used since no determination was reached as to what cases should be excluded, but rather a trap was set to catch the very class of cases which should never have had the remedy in its original crude form. I refer to the precaution announced in the first instructions that preference should be given to hospital cases where patients were to be kept in bed during the "reactions," in apparent neglect if not ignorance of the necessity of elimination, and the ever present need of recognizing other associated causative agencies, chief of which is that of climate. The concealed and therefore more serious tubercular lesions would be brought to light by the searching specific, and cheesy or tubercular pneumonias which would necessarily have to undergo the expected process of "necrosis" would in some way (?) have to be taken care of. Indeed the indiscriminate use of tuberculin was an absurd and indefensible proposition under the conditions specified. I abandoned Koch's proposed method within a month of its commencement, and thereafter refused to give the treatment unless patients were well enough to come to my office and could take exercise enough to eliminate the tubercular bacilli or their toxins when thrown off or set loose by the special agency used.¹

So tuberculin is said to be a failure and the perennial essayist, in assumed wisdom, which seems almost ludicrous to one who knows the truth, exclaims, "Hic jacit" tuberculin the chief of specifics for consumption! As to the original product, should any professional brother desire to investigate the proofs, I can select for him a dozen or more persons, who were once actively tubercular, and who from seven to four years ago were treated hypodermatically with relatively large quantities of the crude tuberculin and who are now apparently well and free from any sign of tuberculosis.

As a result of these years of investigation of tuberculosis by such eminent men as Klebs, Trudeau, Von Ruck and Whittaker, there is no doubt in my mind that the healing specific, the immunizing agency, lies somewhere in the bodies of the tubercle bacilli. Koch practically acknowledges this when he uses the whole of the germ to make his new tuberculin T. R., a product in reality the clear portion of an *emulsion* of the bodies of the bacilli.

While among veterinarians the crude tuberculin has been generally used and acknowledged as the best diagnostic means ever found for the detection of tuberculosis in cattle (a diagnosis that I have thus far utilized with satisfactory result in twenty-one human beings), yet the successful application of the remedy in the arrest of human tuberculosis has been made but by very few. Those who have had the courage, intuition and skill to succeed in this line are well represented by Dr. James T. Whittaker of Cincinnati, who answered the objections to the use of tuberculin in an excellent paper on "General Impressions from Six Years use of the Old Tuberculin," read before the British Medical Association at Montreal, Sept. 2, 1897. He concludes in these words, "aside from the objections urged by ignorant and prejudiced people, not worthy of notice, four apparently valid arguments accumulated, in the course of time, against the use of tuberculin in man.

"1. That the reaction occurred in the absence of tuberculosis. This objection has been met by the demonstration of concealed deposits.

"2. That the reaction occurs in other diseases, syphilis, lepra, actinomycosis, etc. This objection has been met by the demonstration of tuberculosis coincident with or complicating these maladies.

"3. That the reaction will occur in the most quiescent cases even where the bacilli are not only concealed but encapsulated and deposits are partly calcified. This is no objection at all, but a most striking confirmation.

"4. That the use of it is dangerous; that it not only awakens the disease from latent sources but disseminates it over the body and this leads to an infection and increases the danger of infection of others. This conclusion rests on a false premise and confounds the *post* with the *propter hoc*." I have quoted so much because this verdict, like everything Dr. Whittaker writes, is a clearer statement than I could make; but I can heartily endorse it, for during the same long period there has been no time during which I have not had from half a dozen to twenty tubercular patients undergoing this form of immunization by means of some form or derivative of tuberculin.

It has been my desire, if possible, to find such a derivative from or modification of tuberculin, uniform, standard, and freed from all undesirable qualities, as will be acknowledged by the medical world to be a true specific for tuberculosis. I mean just as much an antitoxin for this chronic and perplexingly variable infection, as, in its way, is the antitoxin for diphtheria for that acute and unique disease. You may assert that, with the necessity for a congenial soil for tubercular infection before the disease can find lodgement, and with all the varying complications of susceptibility, of natural resistance, of climate, of age and associated conditions—different in every one of a thousand cases—that the thing is impossible, I believe it is possible and that all these varying conditions are simply elements to be duly weighed and accounted for in our battle against this insidious disease.

There are a dozen, more or less, of tuberculin preparations, extracts or serums, which I have to mention.

1. The crude or original tuberculin of Koch, which is the glycerin extract of the dead bacilli, as I understand, filtered through porcelain.

2. Then comes Klebs' first modification, a purified article called tuberculocidin, in which the crude tuberculin is deprived of much of its toxins and reactionary power.

3. Following this is the name antiphthisin which Klebs gave to practically the same product manufactured in this country.

4. Tuberculinum purificatum, which name Dr. Karl von Ruck of Asheville, has given to his manufacture of practically the same preparation.²

5. A purified tuberculin made by Dr. Whitman of Los Angeles, Cal., from the culture fluid in which the bacilli have been grown, not yet standard in strength but which I have found to be moderately efficient.

6. Oxytuberculin,³ the lately much talked about

² We understand this is made as follows:

"Take the entire ripe culture of tubercle bacilli and transfer to vacuum apparatus, and concentrate to 1-10 of the bulk at 55 degrees C. This takes about a month; remove from vacuum and filter through paper for removal of bacilli, and next through porcelain. Now precipitate with acid solution of sodic iodid of bismuth and filter. Next neutralize the acid solution for reprecipitation of bismuth salts and filter. Next precipitate with absolute alcohol adding enough to bring the entire bulk to 90 per cent. alcohol; let stand and when precipitate has formed, filter. Collect, precipitate and wash it with more alcohol (absolute) dry, weigh and make 1 per cent. watery solution and filter. It (purified tuberculin) differs from antiphthisin in that it is made and concentrated with the tubercle bacilli in the fluid and it is filtered through porcelain as well as paper. It differs from tuberculocidin, in that it is prepared and concentrated at a low temperature (50 degrees C.) instead of at (100 degrees C.) boiling temperature, and filtered through porcelain.

remedy of Dr. Hirschfelder of California, in which a small per cent. (said to be 5) of tuberculin is, under great and protracted heat, saturated with peroxid of hydrogen. The effect of this, if any, besides that of the contained tuberculin, the discoverer claims, is the conversion of the toxin into an antitoxin. This increase of curative effect but slightly shown by my own limited use of the remedy, as I have had only a four-weeks trial of it in a single case. So far, however, the result is not unfavorable. If this creation of an antitoxin outside of an animal body is verified, it is indeed a wonderful discovery; then it is to be hoped that the bulky dose prescribed for injection will be reduced to 1 c.c. or thereabouts. It is not impossible that the excessive oxydation has simply destroyed the toxins, and so left a large amount of a healing property, not yet fully understood but common to so large a bulk of tuberculin.

7. Koch's new tuberculin T.R., descriptions of which you have lately seen in the medical press.

8. Dr. Karl von Ruck's watery extract of the bodies of the dead bacilli, which is a like powerful remedy in immunizing strength to the new tuberculin (T. R.) and I judge will compare favorably, with the same.

This extract is liable to give reactions in susceptible persons, for it is highly charged with immunizing power.³ I have tried the procedure recommended by von Ruck and found it in the main quite satisfactory, namely to commence with the purified tuberculin and work up from 1-10 c.c. to 2 c.c. and then every second or third day give 1-10 c.c. of this stronger undiluted extract, possibly working up to 3-10 to 5-10 c.c. as a terminating dose, the intervals between treatments being lengthened toward the close of the course.

I will explain why I have not used Koch's new tuberculin (T. R.) While the fact previously cited, that the bodies of the bacilli contain the immunizing or healing principle, may be proven by the claimed improved effect of the new over the old tuberculin, yet the admitted fact remains that it is practically an emulsion which Dr. Fisch says is essential according to Koch's intentions and that its curative power would be lessened by filtering through porcelain. Drs. Trudeau and Baldwin (*Medical News*, Aug. 28, 1897) claim to have found the fragments and the whole bacilli in it by microscopic examination. While this would not deter me from using it in an understood case, where the infection was already so great that thousands of bacilli were known to be thrown off daily in the sputum, yet I do not like the technique of its administration nor the idea of my diagnosis being "hedged" against by such a range of dose, equivalent to 1 to 500,000, as Koch (from his experience with the average medical man) has deemed it best to establish. The finally accepted remedy should, I think, be not so liable to deteriorate; it should be stable, uniform, made entirely safe by careful filtration, and the range of dose need not exceed 1 to 1,000 or less.

I am aware that Trudeau has claimed that antiphthisin is only a very weak tuberculin, but in my considerable experience with it and the tuberculinum purificatum during the past four years, in comparison

with the use of crude tuberculin during the previous three years, I have been satisfied that it was safer, that there was less resulting general reaction as well as local reaction in affected areas. The distinctive tuberculosis temperature is apparently more easily controlled by its use.⁵

The tuberculin products thus far considered, with the possible (?) exception of oxytuberculin, are supposed to work by their toxin creating or stimulating the production of an antitoxin in the blood of an affected person. We now mention an additional class where the antitoxin has already been produced in an animal's blood, preferably one already immune, and then through its serum made available in the treatment of tuberculosis. I believe it is possible to do this, as is the case with diphtheria. Whether it is preferable to making the affected system create the antitoxin, I will not attempt here to discuss. It is a difficult and important point to decide. I have seen some persons (previously under the tuberculin treatment) who seemed after some months to be losing their thereby acquired immunity, and whose systems seemed to respond to a renewal of the treatment, as though that particular stimulant to antitoxin activity was just the influence needed. Whether an artificially created antitoxin introduced from without the human body will have an equal or a better effect I have yet to learn.

However, from the many investigations thus far made with serums, we are enabled to assume that an efficient antitoxin to tuberculosis can be produced in the serum of an animal's blood, but it is yet undetermined how much of this effect is purely antitoxic and what proportion of it is transmitted tuberculin. The question of transmission would seem to be relative, the size of the animal treated, and the character and amount of the toxin administered, together with the time before and again after treatment with reference to the taking of serum, all being important considerations. This, too, is a difficult question to decide, for the toxin, if transmitted, may be wholly or only partially neutralized by the antitoxin created in the animal's blood. E. Müller (*Jahrbuch f. Kinderheilkunde*, Vol. xlv) claims, from a study of the blood of children treated with the antitoxin of diphtheria, that the time of the excretion of the antitoxin varies in different individuals, even of the same age and body weight, and that there is no direct connection between the size of the dose of the antitoxin and the duration of the power of immunity, *i. e.*, the time the antitoxin remains in the blood. He shows the protective power of the blood on successive days of a number of individuals, sufficient antitoxin to confer immunity seldom remaining after three weeks. Should we not bear in mind that this study was for diphtheria, comparatively active in its toxicity, and admit for a more chronic disease, as tuberculosis, a similar variability in its antitoxic and immunity laws commensurate with its chronicity?⁶

³ Transactions California State Medical Society, 1897.

⁴ In making this extract virulent cultures are used and the proteids (it is claimed 80 to 90 per cent. of them) are extracted with ether from the filtered bacilli. After repeated dryings on porcelain plates, the filtrates (bacilli) are repeatedly powdered and mucrated over permanent water baths and the resulting proteids are passed through porcelain in a perfect watery solution which is then made to a standard strength watery extract, which when used, can be still further diluted if desired.

⁵ For cases in illustration of these favorable effects reference is made to my previous paper on these subjects. "Tuberculin and the Living Cell," Transactions of the Am. Climatological Assn., 1892, and "Antiphthisin," Medical Record, July 20, 1895.

⁶ Over four years ago, learning from experiments on healthy puppies that they would stand for their size, very large doses of Koch's tuberculin, I conceived the idea that the toxin in this extract might be thus neutralized and a beneficial change in the tuberculin treatment result. I went to the expense of having a healthy pup treated in the course of seventy-two hours, with about 1 c.c. tuberculin to the pound weight. Twenty-four hours afterward the pup was killed and all his serum taken. This was nicely done for me by the New York Biologic and Vaccine Institute. Though no harm resulted from the use of this serum, it was not a brilliant success, for I got the rash, which serums so often cause, and what I thought was a lack of the

Of late the proper technique of serum production is being gradually determined and we have now several antitubercular serums which have gained for themselves a curative reputation.

In Italy Maragliano's serum, made at first from a goat's blood (as I understand it), is now obtained from the immunized horse. Maragliano's results with the goat's serum speak very well indeed for his product and the proportion of successes were about the same, but no better, so far as I could determine, than ours in this country with antiphthisin or purified tuberculin. Furthermore the absence of definite knowledge of the manufacture, strength and dosage of his serum, precluded my own trial of it. This is the "cure" which has lately been lauded to the skies by the sensational newspaper claims of a New York daily.

10. The antitubercle serum of Paul Paquin, though one of the first made in this country and tried by many physicians, I have no personal knowledge of except from results (mostly favorable) observed in a number of patients coming under my observation after they had been treated with it. These results were not distinguishable from those of crude tuberculin, and I can not say that there was not the transmitted effect previously referred to.

11. Professor Crandall, also of St. Louis, immunized a horse I believe with tuberculin (?) taking some two years for the process before the serum was used. I gave it a faithful trial. The results were not bad, nor were they as good as with the purified tuberculin. I could not determine that there was any "transmitted" effect of tuberculin, but I got the serum rash in two out of five cases treated.

12. The H. K. Mulford Company, of Philadelphia, have been faithfully perfecting a serum. To produce this they chose asses as the animals most immune to tuberculosis. When in Philadelphia last June, I examined these animals at their bacteriologic laboratory and was one of the first to try their perfected serum. Its effect was better than that of any serum previously tried; seemed to raise the patient into an exalted state, hopeful of recovery, with physical signs and ability to do, perceptibly improved. This was strongly shown in two young men of the five cases treated, who were hopelessly advanced in tuberculosis, both of whom had large excavations in the lungs. One of these afterward went home to die, and the other has improved by living among the foot-hills and having an injection of this ass's serum once or twice a week. The objection to this serum is its lack of sustained effect and the serum rash, which occurred in one or two cases.

13. We now come to consider the last and I think the best of the antitubercular serums, the antiphthisic serum (T. R.) made by the John T. Milliken Company of St. Louis, according to the formula of Dr. Carl Fisch. In his address, read before the Mississippi Valley Medical Association, at Louisville last October, Dr. Fisch presented the tabulated results of an elaborate animal experiment, or test of this new serum. The serum is peculiar in that the selected horses from which it is taken have been strongly immunized, charged with Koch's new tuberculin (T. R.), the process usually taking four months and the serum being drawn fourteen to twenty-eight days after the

last injection. When it is considered that for a last dose 50 c.c. of tuberculin T. R. was given the horse, which I am informed has now been increased to 100 c.c., we can get some idea of the enormous load of tuberculin these animals are carrying in the blood by remembering that according to Koch, the initial dose of tuberculin T. R. should be 1-500 of a milligram.

Between one and two hundred guinea pigs were used in Dr. Fisch's interesting test.

1. The T. R. serum was shown not to increase but rather to lessen the temperature of a healthy guinea pig for the first three to nine hours.

2. Guinea pigs previously immunized with T. R. serum withstood without harm fatal doses of virulent tubercle bacilli virus, while the control animals died in twenty-one to twenty-four days.

3. The least quantity of T. R. serum needed, previous to the poisoning of the guinea pig, to sufficiently immunize him was determined: $2\frac{1}{2}$ c.c. in five injections during the previous month being sufficient to keep alive and healthy a 600 gram weight guinea pig.

4. The T. R. serum and virus were injected mixed and the proportion of the former sufficient to neutralize a fatal dose of the latter was thus determined *i.e.*, from $\frac{1}{4}$ to 1 c.c. of the serum.

5. Separate injections of the serum proved that (even commencing the tenth day after guinea pigs had received the fatal injections of the poison) they lived while the controls died in from twenty to twenty-eight days, as well as three controls treated with Paquin's serum, after the fatal toxin had been administered to them four days.

6. The serum treatment was shown to have a lowering effect on the abnormal temperature of these poisoned guinea pigs, *i.e.*, from the second to the sixth day a total average decrease each of 2 degrees F.

7. The amount of T. R. serum which would inhibit the poisonous effect of tubercle bacilli and also which would inhibit the reaction to tuberculin was determined; all of which constitutes an experiment calculated to fill us with hope for the trial of this new serum on human beings. Dr. Fisch claims that if there are reactions to T. R. serum which he does not ordinarily find in the affected human being, that they are not the same as from the crude or old tuberculin. To me it does not seem to be so harmful if there are some slight reactions according to the dose given and the susceptibility of the patient, just as we would expect from this remedy; for even if the tuberculin T. R. has not all been neutralized or changed to an antitoxin in the animal's blood, we have a stable, soluble, preservable in standard strength remedy, chiefly in antitoxic form, one which can be relied upon for immunization against tuberculosis, and safe compared with Koch's new tuberculin. How permanent its effect will be has to be left for the lapse of sufficient time to determine. The half dozen cases I have to report on, are not claimed to establish a cure, especially as I have never allowed myself to abandon other and important means of relief simply because I happened to be giving any of these forms of tuberculin. We need all the help that the proper individualizing of a patient will suggest, and we will contentedly bear the charge, sure to be made, that the always admitted essential aids, the preferable climate with good feeding, systemized exercise (including proper inhaling), and hopeful conditions or environments have done it all.

distinctive healing sounds I had expected to find in the affected lung, and so went no further with it.

Case 1.—S. H. F., aged 48; machinist. From Indiana, one month in Colorado when first seen by me July 28 last. His lung disease is said to have commenced with a chill and fever May 1. He is not improving, I think because of tubercular pleurisy at base of right lung, the apex of which is excavated, and top of the other lung slightly affected. A case of laryngeal tuberculosis as well, with nasal complications, bilious temperament and torpid liver. Not a favorable case by any means, when one considers that the daily ounce of purulent expectoration contained fifty-five tubercle bacilli "to the field" on September 15, when the antiphthisic serum T. R. was first administered. The injections were given every alternate day below the shoulder blade commencing with $\frac{1}{2}$ c.c. and gradually increased until a decided reaction limit was found at $1\frac{1}{2}$ c.c. Reaction temperatures inclined to be prolonged of $1\frac{1}{2}$ to 3 degrees F., were found after $1\frac{1}{2}$ up to 17-10 c.c. doses, and I learned that I had a more powerful serum to contend with than I had ever used before. A return to 1 c.c. for the dose gave better results with no temperature rise above 99 for quite a while. Meanwhile up to October 30, he had received 25 c.c. in twenty-one injections, the sputum had greatly diminished in quantity and showed "ten to field" in about two weeks and "one to field" in six weeks. The pleurisy had subsided, partly at least, controlled by wearing a restraining bandage devised to specially limit the movement of the affected area. The effect was good and all the physical signs improved. Unfortunately this patient had to go back to his Indiana home, October 30, but he is still having the remedy administered there and reports improvement continued, with a gain in weight of twelve pounds since the commencement of the treatment.

Case 2.—F. J. M., aged 24; draftsman. Came to Colorado in May, 1897, from Massachusetts. Lung trouble probably dated back to pneumonia five years ago, and a severe cold one year ago. Decrease in weight of twenty-four pounds from his average to 108 pounds, both apices show an advanced fibro-tuberculosis, the third stage being more marked on the right than on the left side. By this evidence the diagnosis of a non-active fibro-tuberculosis both sides was made. Serum T. R. has been given for its general effect with the result that we now have a diminution of expectoration and some improvement. The proportion of the very few bacilli in sputum not yet much changed, improvement in physical signs but no gain in weight, though bad environments and confined occupation, leading to frequent colds, are disturbing elements which have to be accounted for in this case.

Case 3.—Sept. 20, 1897. Mrs. H. Age 27. Came from Connecticut. Weight at this date ninety-nine pounds. Had a hacking cough for eleven years, and two years ago sympathetic whooping cough and fever at times. Now some restrained action at base of right lung where once she had pleurisy, but the chief trouble is a chronic catarrhal fibro-tuberculosis, second stage, upper half of left lung, with softening spot threatening under left shoulder blade. Commenced the T. R. serum September 22, and on alternate days gradually reached 1 c.c. for a dose which has not been exceeded. Bacilli to the field, seventeen large with streptococci and staphylococci. November 2 and 18, seven and eight to the field, small and beaded and less "mixed" infection. November 28, the record contains this note—Has taken 27 c.c. antiphthisic serum and has now no reactions and physical signs have all improved. The temperature being below 99 degrees P.M. and weight now is 106 pounds.

Case 4.—J. A. R. Chemist, age 28, came from New Orleans, July 6, 1897. First seen by me September 18. A case of tubercular broncho-fibrosis of six years standing with hemorrhagic tendency, first stage; both upper halves of the lungs, chiefly right. Up to date taken the T. R. serum treatment ten weeks every other day since September 19. The spirometrical record has improved from 170 cubic inches to 200. He has improved in weight and in general as well as local signs. The record of his sputum examinations is as follows: September 18, 25.3 to the field; September 30, 20.3 to the field; October 18, 2.5 to the field. November 2 and 19, one to five and one to ten fields. December 3, 4 to field (been confining himself too closely indoors.)

Case 5.—J. E. L. Age 24. Newspaper reporter. Came from Pennsylvania. July 4. A case of laryngeal tuberculosis with broncho-fibrosis originating some two years ago but aggravated by overwork at night, one year ago. First stage, left side chiefly affected, but evidences of bronchial involvement top of both lungs. Has taken the serum treatment over six weeks (18 c.c.) with exercise, inhaling, etc.; doing well. Had left side pleurisy at one time which has disappeared. Expectoration much lessened in quantity, chest sounds improved, weight increased six pounds. No elevation of temperature now, though there was a little during the first part of the treatment; voice which was quite hoarse has improved and strengthened.

Bacilli to field October 13, seven, November 20, one to three fields. December 14 none.

Case 6.—W. S. Book-keeper. Age 31. Arrived from Wisconsin, October 28. A case of tubercular broncho-fibrosis with suspicious laryngeal complication, both lungs affected in first stage, also has fistula in ano. Acclimatization may have something to do with his improvement for it has certainly been remarkable. Before giving the serum injection his temperature each day was from 98.5 degrees to 100.5 degrees and by the time 1 c.c. dose was reached the next day's rise was slightly increased. Since then 99.2 degrees has not been exceeded. December 3, after 12 c.c. had been given, the record showed, weight increased 156 pounds, a gain of six pounds in one month. Fistula nearly stopped discharging, sputum lessened in quantity about five times, and the bacilli in it reduced from 23.2 to 2.8 to the field. The physical signs and general strength are also on the gain. In fact the outlook for this, as well as for the others of this group, is bright for a permanent arrest of the disease. There have been five or six others who have taken the same treatment for shorter periods, but not long enough for any definite results. One of them, however, shows great susceptibility and the diagnostic effect of the T.R. serum which is worthy of notice.

A gentleman aged 26, referred to me by his physician in Pennsylvania, was seen on October 22, having arrived in Denver two days previously. His trouble seemed to have originated ten months previously, and he had visited North Carolina without benefit. A laryngeal and pharyngeal tuberculosis with lung involvement very slight at both apices, with principal centering point in left inter-scapular region, seemed to me at my first examination to be all that there was to explain the case. But the effect of the T. R. serum injections made manifest the incompleteness of my search as well as that of several physicians who had examined him previously, namely, that I could not reach the 1 c.c. dose the general and fever reactions were so great and prolonged. At two times, after 7-10 and 6-10 c.c. injections, he informed me he had stayed in bed all day, he felt so ill and feverish, the grippy signs being similar to occasional reactions I have seen from the the old tuberculin. I felt confident there was a concealed cause somewhere. This the stethoscope finally revealed in the left infra-mammary region, where, over an area, not larger than a silver dollar, pleuritic friction with fine crackles were heard only at the end of forced inspiration, and without any pain. Under proper restraint, to promote adhesion and limit movement, I think this condition is gradually improving and that this case will also be a favorable one.

In closing I will add that this diagnostic power, a valuable evidence of the real efficiency of the new remedy, together with the infrequency of the resulting serum rash (though local reaction, infiltration, etc., at the point of needle puncture will sometimes be seen), is or ought to be a recommendation for this T. R. made serum; especially to those physicians who understand its import. That this preparation can be made standard and safe will also do much toward overcoming the natural prejudice which pertains to the use of either Koch's old or new tuberculin.

HOW WE TREAT CONSUMPTIVES TODAY.

Read before the Tri-State Medical Association of Alabama, Georgia and Tennessee, at Nashville, Tenn., Oct. 13, 1897.

BY PAUL PAQUIN, M.D.

ST. LOUIS, MO.

From the very beginning of the application of anti-toxins in diphtheria, tetanus and other infections, it was hoped that it would also be beneficial in tuberculosis, and to that end many investigators have

labored faithfully in all parts of the world. Maragliano, in Italy, first sought a remedy in the natural blood serum of the ass, and in the latter part of 1885 or in 1886, he reported the results of his work with the serum of the same animal, previously treated to increase immunization. Prior to this, however, Richet, Héricourt and others in Europe had used the natural dog blood serum in various forms of the disease. I began to immunize horses against this affection in 1894, and in January, 1895, reported the first clinical results with the first immunized horse blood serum ever obtained or used, so far as I am able to learn. Many criticisms, kind and unkind, and unwarranted reflections scarcely dignified, followed, and some have stooped to public persecution, but the work has progressed. Today, amidst the puerile denunciations of sciologists, I have the consolation of finding my humble researches respectfully considered by some of the leading scientific lights of Europe and America and, the results obtained with it, attested by conscientious clinicians of high reputation in many quarters of this and other countries.

In spite of the beneficial effects of climate and other forms of treatment in vogue, and the vaunted claims of recoveries said to have been produced by a hundred different processes, there seems to be no doubt that sero-therapy, being nature's own remedy in infections, is the most promising. None of the other therapeutic measures used seem to offer so much hope or confidence. A seventh of the population die from the effects of consumption in one form or another, and probably four-fifths of this percentage succumb to the disease affecting the respiratory organs. Such an excessive mortality due to one disease warranted the beginning and continuation of my experiments, and investigations by the whole profession, in any legitimate line, for the discovery of a treatment that shall subdue suffering, reduce the mortality and arrest the progress of inherited conditions of tuberculosis.

Tuberculosis may affect all the organs of the body, but its seat of preference is in the chest. The respiratory organs of this cavity offer, apparently, the best field for the germs to grow, and more beings succumb to pulmonary phthisis than to all the other forms of tuberculosis together. It is this form I shall consider chiefly in this paper. It is the kind we see every day.

First, what is the nature of pulmonary phthisis? It is, unfortunately, nearly always a complicated affection, even in the very early stages. Very early in the development of the disease, we find associated with the bacilli of tuberculosis a number of other germs, among which some are as deadly and as destructive as the specific microbe. Comparatively speaking, tuberculosis is essentially a slow malady, even in acute cases. Its primary lesions consist of one or several local points of inflammation, due to the growth and multiplication of the bacilli, which occurs at the expense of the cells, their secretions and products, among which the germs are lodged. During this development, toxins are generated. They are poisonous, as the name indicates, and they cause the death of the cells around them and these, eventually, soften and become liquefied. It is thus that we obtain the first formation of caseous matter of pure tuberculosis which, in such conditions, is not mixed with the products or pus of the ordinary septic or pyogenic germs. During this first evolution of a case of tuberculosis,

at its initial point of infection, a protective envelope is formed by nature's recuperative forces, and it is soon such as to surround the lesion, thus circumscribing it and limiting the pathologic development. Then we have formed a tubercle, which may vary in size from that of a point of a pin to a walnut or larger, the most voluminous nodules being usually the result of the junction of several small tubercles or their coalescence. If a section is made through tubercles at various stages of their development, it will be found that from a hard consistency at the beginning they gradually soften and, so far as germs are concerned, they first contain only the bacilli of tuberculosis. But, when softening of these tubercles takes place to the degree that their envelope ruptures, there is offered to the germs which are inhaled, a means of ingress into diseased tissues which are fit soil for the latter's development. This is the beginning of mixed infection. From that time on, the expectoration of a patient not only demonstrates the existence of consumption germs, but large numbers of other pathogenic microbes, such as the streptococcus, staphylococcus, the tetragenus and numerous other complicating organisms more or less effective in their power to destroy tissues. Such complications seem to be of tremendous power in the causation of softening of large areas of lung tissue and in the production of cavities. Then, we have to deal not only with the associated microbes and the lesions they produce, but also with the toxins which they generate and which, separately or collectively or, perhaps, in chemic combination, produce various forms of toxemia and alter the blood, the nervous system and, as a consequence, affects the whole organization banefully in a more or less pronounced manner.

Tuberculosis in the early stages, before serious microbic complications arise, produces as a rule a comparatively mild fever, the temperature seldom rising above 101 degrees F. When the complications appear, the temperature rises to 102 degrees F., 103 degrees F. and higher, according to the degree of infection, the extent of the lesions produced and the quantity and quality of the toxins. It is not necessary for the purposes of this paper, to go deeply into the pathology of tubercular developments. I merely desire to impress you with the importance of recognizing the nature of the lesions and other pathologic conditions, in a general and special way, before applying any remedy, and also the necessity of considering the peculiarities of each individual case, in order that the disease be not treated only on a general plan supposed to be applicable to all; but rather that each individual case be treated on its merits. It is not enough to treat consumptives as such. One should treat the patient against the general and special diseased conditions existing. The local lesions and the special effects thereof; the direct results of tubercular development upon remote organs or systems; the general depression dependent on such conditions; the individual characteristics and mode of life; the inherited predispositions; all these should be considered before instituting treatment. The disease yields or resists very differently, according to the nature of the infection, its effects and the peculiarities of the patient's individuality. It is needless to say, for instance, that patients who have inherited the elements that predispose to tuberculosis do not offer the same physical resistance to the destructive power of the germ of this disease as do those unfortunate who

have contracted the malady by accident and have more vital energy. In concluding this preface to the discussion of the treatment of tuberculosis, I wish to say a word with reference to the method of producing the antitoxins which are most suitable for the treatment of consumption.

As stated above, my first publication on the subject of serum in tuberculosis was made early in 1895. At that time, I was not ready to publish in detail the *modus operandi* of the laboratory processes. Since then I have repeatedly, at various medical meetings and through the medical press, explained more or less fully the various methods of immunization which I have tested from time to time. In 1894, I realized that the simple use of toxins in the treatment of the horses used for the production of antitoxin was not sufficient to produce complete immunity because it had been demonstrated that not only the liquid toxin (viz., tuberculin) of the germ of consumption was poisonous, but also that the structure of the parasite contained poisonous elements of a deadly character. Thus it was, that very early in my work, I used not only tuberculin for injections of the animals used to produce antitoxic serum, but used besides the structure of dead germs or germs with vitality purposely lowered and then mixed with sterile water. I have used the live germs also, following injection of these solutions. Thus it will be seen, that at the beginning, I used chiefly tuberculin to immunize the horse, gradually adopting methods which insured, more and more, the effects of reaction upon both the liquid poisons and the germ substance. Some tuberculins I used at the outset were produced by recognized authorities; chiefly such as Koch and the Bureau of Animal Industry in Washington. By the mixture of these liquid toxins and the germs, seriously modified or not, all the elements of the tubercle bacillus entered into the immunizing agent. But a question of importance, with respect to the reaction of the animal to these injections arose during that work, and it was this: What proportion of the toxic element of the germs was absorbed by the economy of the horse? It was evident that the greatest quantity of the most virulent quality of all the tubercle toxins, be absorbed in order to produce the greatest reaction and the highest immunity. Koch of Berlin gave help to the production of more perfect immunizing material when he brought forth his new tuberculin, which he specifies under the name of T.R. This, according to the publications which have appeared, is nothing more than the poison in the structure of the germs of tuberculosis extracted by rubbing these germs in a mortar, and by centrifugalization means. For use, this preparation is mixed with sterile water or glycerin, or both, and may be preserved by the addition of a minute proportion of formaldehyde or .3 to .4 per cent. of trikresol (as is the case for the preservation of the serum itself). The object of this pulverization of the germ structure is to liberate the toxin as much as possible and facilitate the absorption and assimilation of every toxic principle they contain. We produced practically the same thing at the laboratories under my control, for at least two years, for the purpose of immunizing horses.

By injecting a mixture of tuberculin and pulverized germ substance into a horse, in doses varying from one cubic centimeter daily or periodically to thirty or more, during from two to four or six months, we get a blood with serum that has resisting

powers more or less pronounced, against the development of tuberculosis.

Now, as to the treatment of the disease. Bearing in mind the essential factors that contribute to the pathology of tuberculosis and the various circumstances that may influence it, how should we treat the disease today? Is sero-therapy promising enough to warrant its use and warrant further experiments and investigations? Yes. If it arrests one case in a certain stage does it, therefore, promise to arrest another in a similar stage, irrespective of other influences favoring destruction? No. There is no one treatment applicable to all forms of tuberculosis, irrespective of the conditions complicating or influencing the malady, or irrespective of the actual pathologic conditions locally. Anti-tubercle serum can be justly expected to act only against the purely tuberculous processes, and this, by no other means than the usual physiologic interference which nature herself sets forth to neutralize the toxic products of infections and subdue the microbic invasions. Sero-therapy in the treatment of consumption has its reason of existence because it is based on natural law. Yet it should be sustained by such forms of special and general treatments as the conditions present may demand. This assistance is useful to facilitate and hasten the repair of the damage done to the organization. True, we have on record apparently complete recoveries from serious conditions, which have occurred after the exclusive use of anti-tubercle serum or serums for mixed infection; but we have a greater number of such recoveries and more numerous improvements as the result of scientific management of the patients and a properly combined treatment including serum as special medication. A patient may recover by the effect of serum alone, when the result of the disease is not such as to affect organs or systems of paramount importance, such as the lungs, the throat, the circulation, the nerves, the stomach, etc., so severely, as to preclude the possibility of their restoration by nature's own force, after the baneful effects of germs and their toxins have been removed by the antitoxin. If such organs or apparatus are diseased practically beyond repair, particularly when mixed infection exists to a serious degree, anti-tubercle serum, if it does arrest the progress of the tubercle bacilli, can not directly repair the physical and physiologic loss of the tissues and their vitality, and death may ensue. Here is where accessory treatments are needed. If there be a mixed infection and serum is tried, a serum prepared specially for this condition is essential, such as the anti-streptococcus serum, which is produced on the same general principle as that for tuberculosis or diphtheria, and which is applicable in many of the usual mixed infections of any disease.

The aim of sero-therapy in tuberculosis then is, first of all, to counteract the effect of the toxin; second, to interfere with the progress of germ life; third, to restore or create anew in the organization physiologic recuperative powers, thus assisting in restoring the equilibrium of the faculties and the vitality of the organization as a whole. It is plain, therefore, that the serum treatment, like all others, promises most in the earliest stages.

From all that precedes in this paper, it would seem evident that in the treatment of consumption one should, first of all, pursue a wise course of management, and second, general and special treatments suitable to each case. Indeed, it may be stated as an

axiom, that all the hygienic influences that may be brought to bear on the system to improve its vital powers, should be directed to play their part.

GENERAL TREATMENT.

Climate is a point which most practitioners justly insist on being properly considered. Dry climate, free from the sand and dust storms should be chosen, if practicable. It may be hot or cold; both are beneficial in different classes of patients. It should be remembered that some tuberculous patients suffer much from heat or cold, according to their condition, and others the reverse. As a rule, emaciated, anemic patients prefer a warm temperature and stand the effects of cold very poorly, while those with more flesh and warmer blood thrive more or less under its influence. Altitude is not of so much consequence. Palm Lake, in California, which is below the sea level and yet exceedingly dry, is said to be the most beneficial locality for consumptives, while equally good results are claimed for the altitudes from 2,000 to 10,000 feet as exist in Colorado, New Mexico, Texas and some states of Mexico. The beneficial effects of climate are said to depend chiefly on the germicidal and stimulating properties of ozone and the purity of the air; therefore, it may be obtained, in a measure, in a room in a damp climate, in which such air may be to a degree created, by means of electricity and otherwise.

As a rule, patients are removed to suitable climates when it is too late, when they have cavities and are almost unavoidably doomed. On the other hand, those who do go to such climates usually return home too soon. Indeed, those who migrate to dryer climes for lung diseases should remain there if it agrees with them. They should make it their home. To return from such places to dampness usually means relapse and death.

Hydrotherapy is sometimes useful in consumption, particularly in the earlier stages, and more especially in those who have contracted the disease by contagion, without there being any inherited field for it. Then, salt rubs, all over the body, followed by a cool or cold douche or plunge of from one to five minutes duration, and then by a coarse towel friction, assist materially in stimulating the circulation and contribute to the well-being of the sufferer. These should be administered morning or evening.

Massage properly applied is another treatment of much utility, particularly in cases where there is indolence and a disposition to avoid exercise, even though the strength is sufficient to warrant it.

Dietetics are also of very great importance. Generally speaking the diet of consumptives should consist largely of animal albuminoids and heat producers of the most appetizing and nutritious character, the most easily digested and in the smallest bulk. While vegetable albumin is good, animal foods seem to be the most suitable, and among these tender beef, broiled, roasted or boiled, stands, in the order named, pre-eminent. Lamb, chicken and game come next. Fresh fish is also good. Vegetables that are agreeable to the patient and do not disturb digestion should be allowed as part of the diet, but not in sufficient quantity to appease hunger or supplant meats. So it is with sugars and fruits, the latter being preferable. Milk, cream and butter are advisable, if well tolerated. In case of poor appetite, the whites of two to

half a dozen eggs, one to three or four times a day, at meals or between meals, constitute an excellent diet, supplying as it does, a large amount of albumin in a small bulk, usually digestible even by an impaired stomach. These may be given raw or in milk shakes or in the form of punches with a small amount of good sherry wine. Made dishes, fried articles of food, should be avoided. The excessive use of alcoholic stimulants is likewise contra-indicated, and so is tobacco.

SPECIAL TREATMENT.

First in line is the specific treatment: that form of therapeutics which aims to set interference in the way of microbic development. It may consist of prophylactic measures of the vaccinating order, or treatment by the action of immunizing and curative principles, based on the laws underlying immunity and recovery from infections. As vaccinating agents, the various forms of tuberculin may be used. Being poisonous principles of the germ of the disease, their effect is limited to the production of a mild kind of tolerance of the consumption germ, by the system of the being inoculated. Consequently, it is only in the very earliest moment of suspicion of tuberculosis that one may expect a cure by the use of such a preparation. Antitubercle serum, on the contrary, being the product with which nature herself often cures tuberculosis without the guidance of the human hand, may be used in all stages with perfect propriety and safety and with the assurance of at least having done one's duty in the application of medicine. As said before, it is in the earliest stages that the disease can be more readily arrested, but being an antitoxin it is applicable in all stages and under all circumstances, except the very rare exceptions in which heart disease or other idiosyncrasies exist, which preclude the hypodermic injection of albuminoids or salty preparations, and sometimes even of water.

In cases of pure tuberculosis, anti-tubercle serum may be administered hypodermically, in doses ranging from 5 to 6 ms. daily, 30 being the average maximum dose. The place of injection, when they are to be continued for some time, should be a locality where a heavy fold of the skin can be most easily lifted and the hypodermic needle plunged most deeply into the connecting tissue. I find the area in the back, towards the side, most suitable. See Fig. 1.

The untoward effects of serum injections are very uncommon, particularly if one is careful not to push injections too rapidly and in too large doses from the first. Occasionally, a local swelling occurs which may be reduced by the ordinary methods for such conditions. If precaution has been taken to disinfect the skin thoroughly at the point of injection, by washing the locality and then rubbing it with alcohol, or preferably formaldehyde, there is little chance of producing a swelling due to microbes, providing that the syringe and needle be thoroughly clean and free from germs of any kind. The kind of syringe that appears in Fig. 2 is most suitable. It is easily disinfected, is graduated with both systems; its needles are not so large as those of most instruments and therefore cause less pain. The serum itself is absolutely sterile. No one need fear infectious injury from that source, unless by serious carelessness germs are allowed to contaminate it.

Infrequently symptoms of arthritis develop, which

resemble very much the ordinary symptoms of rheumatism and which subside after suspending injections for a few days, and under the treatment for rheumatism. The occurrence of urticaria and other skin eruptions is not uncommon, and usually avoidable by progressive doses.

Figure 1.

The most striking, peculiar and perhaps most alarming of all the untoward symptoms of sero-therapy in any disease, is the strange and sudden interference with the circulation, manifested by dizziness, almost immediate cyanosis, and sometimes, more or less serious pain along the spinal cord, from the point of injection downward, including the nerve courses of the lower limbs, occasionally producing nausea and pain in the stomach. Sometimes these manifestations are followed by rigor. Fortunately, these results are exceedingly rare and never have proved fatal. Over one hundred thousand injections of serum antitubercle (Paquin) are recorded without a serious result. In

Figure 2.

such cases, I usually discontinue hypodermic medication and use instead rectal injections with special syringe, Fig. 3, which gives as good results in many cases, although it requires usually a larger dose. As treatment of these effects, I prescribe nitrate of strychnia, hypodermically.

In mixed infections, particularly where the germs of pus predominate and where the expectoration is largely made up of pus and broken down tissue, I use the anti-streptococcus serum as accessory treatment. I produce this serum under the same principle that underlies the production of all other antitoxins, namely, by the immunization of the horse, by saturating injections of the toxins and germ substance of the streptococcus. This is done by the method known as Marmorek's, somewhat improved. This serum and the anti-tubercle serum may be mixed or given alternately on alternate days.

As to internal medication, it must depend wholly on the existing conditions. In anemia and other conditions suggesting feebleness of the nervous system and circulation, proper reconstructive blood tonics and nerve stimulants, such as pepto-mangan and nitrate of strychnia, are desirable. As to cough, unless it is very aggravating and prevents sleep to a serious degree, I never use opiates. I usually administer, when absolutely needed, codein and terpinhydrate.

It has been suggested that alteratives be used to assist in arresting the breaking down of tissue and glandular suppuration, etc., as is done in the treatment of syphilis. For that purpose, I have found a solution of iodine properly mixed with glycerin and some of the halogen salts, very beneficial. Iodine is credited, indeed, with having cured tuberculosis. The iodides are not good. They seem to destroy red blood corpuscles.

Figure 3.

As to inhalations, they should never be of an irritant character and, in fact, one should be very careful in their administration. In the early stages of tuberculosis most inhalations produce an irritation of the bronchi which is followed by a secretion that offers a good nidus for the development of germs. The inhaling ingredients containing the essence of pine needles, benzoin and such essences as are not irritant and are of a balsamic character, are most suitable. In cases with cavities, inhalations containing formaldehyde, are useful as disinfectants.

Electricity is also prescribed in tuberculosis. Both the galvanic and faradic currents have been used. The galvanic current is said to act by direct chemic action through the diseased organs, the poles being so placed as to pass the current through the affected parts. The benefits of this treatment are problematical, though sometimes they seem to be favorable. The faradic current is applied in a general way, as a stimulant of the general system.

Of recent date, so-called medicated electricity has been used in tuberculosis. It consists of treating the diseased portions by the application of the galvanic current with poles dipped in certain drugs.

Iodin has been chiefly used for this purpose, and it is said that the current carries with it through the diseased organs principles which tend to arrest the progress of tuberculosis.

In closing, I wish to draw your attention to an exceedingly important point. It is, that most every physician expects too much of sero-therapy in tuberculosis. I have never made extravagant claims for it. It can not perform miracles and should be used early. It is neither just to the patient nor to the treatment to apply it as a last resort, when everything else has failed and the condition of the patient is such that doom stares him in the face.

REPORT ON OXYTUBERCULIN IN THE TREATMENT OF TUBERCULOSIS.

BY J. O. HIRSCHFELDER, M.D.

SAN FRANCISCO, CAL.

SAN FRANCISCO, Nov. 20, 1897.

To the Editor:—I send you herewith a report on Dr. Hirschfelder's oxytuberculin, together with his notes upon the cases examined, which we hope you will publish in full in the *JOURNAL*. We are convinced of its efficacy and value, and urge its extended use. You will observe that it is not in any sense a secret nostrum, but has been placed legitimately before the profession. Yours truly,

HENRY GIBBONS, JR., M.D.

Since the address delivered before the California State Medical Society in April, 1897, upon "Oxytuberculin" the investigations described therein have been continued both in the bacteriologic and clinical departments.

The results that had been obtained up to that time have been confirmed by further observations under the scrutiny of many of my medical brethren.

The laboratory experiments proving the inhibitory action of the oxytuberculin upon the bacilli tuberculosis have been repeated a great number of times with different modifications, but all teaching beyond doubt the certainty of the doctrine that oxytuberculin, even when greatly diluted with the culture medium most favorable for the germ, will prevent its growth. In all, forty-one series, of such culture experiments have been made by me and watched by my colleagues.

Continued treatment of many of the patients whose cases were reported at that meeting have shown that some of them have become entirely or nearly well, many have become much improved, while a few have grown worse or have died. A table of all of these cases, as well as of such as have begun treatment since that time, will be herein reported.

Believing it the duty of Cooper Medical College to investigate the value of oxytuberculin, the faculty of that institution appointed a committee for that purpose, consisting of most of the professors of that institution.

October 24, after the committee had carefully inspected the laboratory evidence, the cases whose histories will be reported in detail in this paper were presented in person to this committee together with stained slides of the sputa prepared before, during and after the treatment. The cases were carefully investigated by the committee in every direction, physical examination of the chest and laryngoscopic examination of the throat being made where it was found necessary.

At the conclusion of this investigation at which a number of medical gentlemen not connected with the college were present and who participated in its deliberations, it was decided that the committee fully

endorses the value of oxytuberculin, but desires to formulate its verbal approval in a lengthy report which shall be presented at the next faculty meeting, to become a matter of permanent record.

It was stated to the committee that I did not underestimate the value of experiments conducted on animals, but that lack of facilities prevented me from conducting these in such a manner that their evidence, positive or negative, would be indubitable.

I stated that I considered it my duty to present all evidence collected, whether it be favorable or unfavorable, that it would not be proper to make a number of animal experiments and to select from these such only as gave favorable results, omitting others because the conditions under which they might have been performed were not such as to exclude accidents.

It has been my custom not to omit any observations that I have made bearing upon the subject, however unfavorable to my method the conditions may have been.

I stated that under the circumstances I deemed it wise not to enter upon the field of animal experiments, but to leave that department to those scientists who might be more favorably equipped for such researches.

The following are the cases that were presented to the committee:

Case 1.—F. A. A., merchant, aged 41; Jan. 15, 1896. No family history of phthisis. His wife died of tuberculosis last October, at which time he was subject to severe mental strain. For the past year he has been troubled with insomnia. For the past twenty years he has had occasional cough, with morning expectoration. Last October patient expectorated 35s of pure blood. During the past six weeks the cough has been worse; he has lost eleven pounds in weight and has had one night sweat. The rectal temperature varies from 99.2 to 100.4 degrees. Examination showed patient to be a fairly well nourished, very pale individual. Head shows no peculiarity. Cervical glands are slightly enlarged; the thorax is long, broad, well arched and deep; the right side is slightly flatter than the left; the right supraclavicular region is slightly sunken; both sides move equally in respiration; there is a slight dulness of the right apex, with faint bronchial respiration and a few rales; the area of cardiac dulness and heart tones is normal; the liver is 10 centimeters and spleen is not enlarged; the urine is normal, the spirometer test shows 3160-3230 c.c., and the hemoglobin 70 per cent. (Gowers' hemoglobinometer); the sputum contains large numbers of bacilli of tuberculosis; his weight is 153½. He was injected with oxytuberculin in doses of 5 c.c. daily, and on January 30, that is, two weeks after the treatment had been begun, he had already much improved, his appetite being better and the patient feeling stronger. His cough was much less and the expectoration about one-third of what it had been before. His weight was 155, the hemoglobin 90 per cent.; at one examination no tubercular bacilli were found in the sputum. February 27 his weight had increased to 161 pounds and the spirometer showed 3260-3380 c.c. At four examinations of the sputum during the month no bacilli tuberculosis were found, and on one occasion only a few. For fifteen days previous to February 29 no expectoration had occurred and the patient felt much stronger. In March the evening rectal temperature reached only to 99.6, and on one occasion he coughed, raising a small quantity of phlegm, which contained a few bacilli. March 31 and April 20 no bacilli were found. May 23 he had a chill and the spleen was found to be enlarged. For this he was given quinin for a while, that being the only medicine he had received during the whole course of the treatment. June 4 was discharged cured, there having been neither cough nor expectoration since April 20. The physical examination made by me and by Professor Kerr of the Medical Department of the University of California showed absolutely normal condition of the lung, no dulness whatsoever being present. The patient returned to his work, has gained further in weight and at the present time feels and looks perfectly well, and has remained so continuously since he was discharged from treatment on April 20, 1895. His present weight is 174 pounds.

Case 2.—Mrs. E. G., age 30, student. June 9, 1896. No family history of phthisis. Patient was well until two years ago when she had a grippé with bronchitis; since then she has been

coughing. She went to Phoenix, Ariz., used antiphthisin and gained eighteen pounds. During this time the cough continued and bacilli had always been present in the sputum. Two weeks ago patient had an attack of croup. The temperature rose to 103 and remained there for four days.

Physical examination.—Patient is a well-developed, well-nourished, excessively pale individual; thorax moderately long, broad, well arched and moderately deep; dulness of the right apex posteriorly to the second dorsal vertebra; dulness of the left apex posteriorly to the first dorsal vertebra; dulness of both apices anteriorly to below the clavicle; bronchial inspiration and expiration of both apices loudest upon the right side; few consonant râles; area of cardiac dulness normal, tones clear; liver not enlarged; spleen extends to the anterior axillary line; pulse feeble; spirometer 2,000 c.c.; hemoglobin 65 per cent. (Gowers); weight 155 pounds; large number of bacilli in the sputum; temperature normal. Injections of 5 c.c. daily were made until July 27. June 16, appetite decidedly better; 20, able to swim further than she had swam in a year; 27, looks and feels better, cough and expectoration less, weight 156½ pounds; July 3, very few bacilli; 20, no dulness of the lungs, vesicular murmur over the left apex, respiratory murmur is harsh over the right apex; 22, 5 mm. of sputum, very few bacilli; 27, weight 159 pounds, spirometer 2350 c.c.; hemoglobin 70 per cent., began with 10 c.c.; August 2, weight 159½; 8, weight 161½; 11, walked two miles, weight 162; September 17, raised small quantity of mucus, no bacilli; 30, weight, 166; October 7, few bacilli; 9, weight 163½; November 7, no bacilli, weight 167; 21, weight 168½; 26, few bacilli, weight 165; December 9, few bacilli; 23, weight 165, injected 30 c.c.; 29 expectorated for the first time in six weeks (2 minims), few bacilli; January 27, weight 162½, few bacilli; February 5, injected 20 c.c.; 15, no bacilli, 5 m. sputum; March 1, 10 c.c., weight 162½; April 6, no bacilli; 7, no dulness of the lungs, murmur vesicular, weight 163½; October 20, no expectoration for many months, looks and feels well, both sides of the thorax move equally, no dulness of the lungs, murmur vesicular.

Dr. Rigdon reported at the meeting that he had examined Mrs. G. before treatment had begun and that a large number of bacilli had been present. He now found none. Both he and Dr. Farnum examined the patient before the committee and pronounced her perfectly well.

Case 3.—H. F. M., age 28, reporter; May 28, 1897. Paternal grandparents and two paternal aunts died of phthisis. Father had some lung trouble between 25 and 35. Well as a boy. At 20 weighed 196. Fall of 1890 and spring of 1891 had two attacks of pleurisy. In the fall of 1892 threatened with pneumonia. Was nearly salivated with mercury. Was in bed one week. Falls of 1893 and 1894 had two severe attacks of throat trouble, had cough for a week. In spring of 1896 had what was called pneumonia. In fall of 1896 had a cold, coughed and had pain in chest. Weight 168 pounds. In April 1897 bacilli were found in the sputum by Dr. Riley. Had cough, expectoration and night sweats. Weight 155. Coughed blood one week ago. Patient is a fairly developed, moderately well-nourished, pale individual; cervical glands slightly enlarged; thorax long, moderately broad, fairly arched, deep; flatness of the left apex posteriorly to the first dorsal vertebra of the right to the second dorsal vertebra; both anteriorly to and including the clavicle; bronchial inspiration and expiration of both apices; May 30, temperature, A.M., 98.5; P.M., 98.2. May 31, temperature, A.M., 98.2; P.M., 99.6; injected 1 mg. tuberculin (Koch); bacilli found in specimen made by Dr. Riley on March 27. June 1, temperature, 8 A.M., 98.2; 10, 98; 12 M., 98.4; 1 P.M., 99.2; 8:15, 99.2; 9 A.M., 99.4; injected 3 mg. tuberculin (Koch). June 2, temperature, 1 A.M., 99.4; 8, 98.4; 9, 98.4; 6:45 P.M., 100.6; 7:45, 100.6; 9, 100.4; 11, 100; has headache; June 3, temperature, 8 A.M., 98.6; 10, 98.6 injected 5 mg. tuberculin (Koch); 6 P.M., 101.2; 7, 100.8; 8, 100.6; 9, 100.2; 10, 100. June 4, temperature, 8 A.M., 99.2; 9:45, 99.6; P.M., 99.6; dulness more extensive and more intense; bronchial respiration is more evident; temperature normal; injected 5 c.c. oxytuberculin. June 5, feels better; injected 10 c.c. June 11, temperature 98.8 to 101. June 19, injected 20 c.c. June 22, no cough for a week; injected 10 c.c. July 9, injected 20 c.c. July 19, cough slight; weight 151½. July 20, took dilute sulphuric acid by mistake. October 11, injected 10 c.c. October 22, no dulness of the lungs, murmur vesicular; weight 156½; feels well.

Case 4.—H. P., age 40, minister; May 6, 1897. Father died of miner's consumption. Well as a boy. For the past few summers patient has had attacks of diarrhea. Patient is a moderately developed, poorly nourished, pale individual;

thorax long, broad, flat, shallow; both supra-clavicular fossae sunken; slight dulness of the uppermost portion of the right apex; bronchial respiration of both apices, more marked upon the right side; heart normal; liver and spleen not enlarged; no bacilli in the sputum.

Injected 1 mg. tuberculin (Koch). May 27, 8 P.M., temperature 97.2; 9 A.M., 97.8; 10, 97.2. May 28, 6 A.M., temperature 97.6; 7, 95.2; 9, 97.8; 10, 96.6; 11, 96.6; 12 M., 98; 1 P.M., 99.2; 2, 98.6; 3, 99.6; 6, 99.8; 8, 101.2. Injected 3 mg. tuberculin (Koch). May 29, 3:30 A.M., temperature 101.4; 6:30, 100; 8, 99.8; 9, 100.2; 3 P.M., 101.4; 8:30, 101.4; 9:30, 100.2. Dulness of the right apex is more pronounced than it was and a dulness is found in the uppermost portion of the left apex, bronchial respiration is louder. May 30, 7 A.M., temperature 100.4; 8 100; 10, 98; 2 P.M., 99; 4, 99.8; 11, 98.8. May 31, 6:30 A.M., 98.2; 10, 97; 12 M., 97.8; 3 P.M., 99; 4, 99.2; 7, 98.6. Injected 6 mg. tuberculin (Koch). June 1, 6 A.M., temperature 99.4; 7, 99.6; 8, 99.6; 9, 101; 10:30, 101.4; 12 M., 102; 1:30 P.M., 102.4; 2:30, 102.2; 3, 102.4. 7, 102.6; 9, 102.2. Flatness of the left apex posteriorly to the first dorsal vertebra; flatness of the right apex posteriorly to the second dorsal vertebra. Loud bronchial respiration of both apices. June 2, 7:30 A.M., temperature 100.8; 8:30, 100.8; 9:30, 100.8; 11, 100.6; 12 M., 100.6; 2:30 P.M., 100.2; 3:30, 100.8; 8:30, 99.6; 10, 98.8. Injected 5 c.c. of oxytuberculin. June 3, 7 A.M., 99; 12 M., 98.4; 2 P.M., 99; 3:30, 98.5. 4:30, 98.9; 9, 99.1; 11, 100.6. Injected 10 c.c. Feels much better. Bacilli found in the sputum. June 4, morning 98.8, afternoon 98. June 5, cough and expectoration much better, feels better. June 7, morning 98.5, afternoon 98.4. Diarrhea better. June 11, morning 101, afternoon 102. Has tonsillitis; gargle ordered. June 13, morning 101.6, afternoon 103. June 14, morning 98, afternoon 98.6. June 19, feels well, no diarrhea. June 21, 22, night sweats. July 6, injected 20 c.c. July 20, has diarrhea. August 13, has diarrhea still, ordered creta. August 14, diarrhea is much better. August 23, diarrhea is worse; ordered pulv. opii, plumbi acet. and tannin, each .065 gram three times a day. September 23, no diarrhea, temperature normal. October 1, no cough or expectoration. October 21, patient feels perfectly well. Examination of the chest shows absolutely normal conditions. No bacilli in the very small quantity of sputum raised.

Case 5.—T. O. P., age 25, April 23, 1897. No heredity. Began to cough in June, 1895; several weeks later had a slight hemorrhage. The cough and expectoration increased and were attended by fever, night sweats and loss of strength. He went to Arizona and improved, but since then the old trouble has continued. Bacilli found in 1893 by Dr. Frey of Washington. Patient is fairly developed, moderately well nourished. Thorax moderately long, broad, well arched, deep. Dulness of both to the first dorsal vertebra anteriorly to the clavicle; faint bronchial respiration of both apices; heart normal; liver and spleen not enlarged; weight 142½ pounds; hemoglobin 70 per cent. (Gowers); sputum contains a moderate number of bacilli; temperature, morning 99.1 to 102. Injected 10 c.c. oxytuberculin. May 27, temperature normal. July 6, feels better; 20 c.c. injected. August 11, small amount of mucus, no bacilli. September 23, 10 c.c. October 11, no bacilli, small amount of mucus. October 19, no dulness of the lung, murmur vesicular. October 22, Weight 142½ pounds.

Case 6.—Mrs. C. H., age 31, May 13, 1897. Maternal grandfather and one half sister died of phthisis. Had the usual diseases of childhood. Eight years ago had a hemorrhage; this was followed by a morning cough which persisted. Four years ago had a second hemorrhage and another three months ago. For the past two months had short breath, even while at rest, the cough and expectoration have been worse and she has had night sweats. Patient is a moderately developed and nourished individual; thorax moderately long, moderately broad, well arched, moderately deep; left side moves decidedly more than the right; dulness of the right apex posteriorly to the second dorsal vertebra, of the left to the first dorsal vertebra; dulness of the right apex anteriorly to the clavicle, of the left to 2 cm. above the clavicle; bronchial respiration of the right apex faint, bronchial of the left; râles heard throughout the right lung; area of cardiac dulness normal, tones clear; liver not enlarged; spleen decidedly enlarged; no abdominal tumor; abdomen not distended; urine normal; hemoglobin 60 per cent. (G.); weight in health 145 pounds, at present 129½; moderate number of bacilli; temperature, morning, 99.6, afternoon 100. Injected 5 c.c. oxytuberculin. May 19, injected 10 c.c. May 26, temperature morning 100.8, afternoon 98.8. Expectoration less. June 1, morning 99, afternoon 101. June 2, injected 20 c.c. June 5, morning 98.6, afternoon 101. June 7, weight 128½ pounds. June 16, coughs less and feels better. June 17, weight 125½ pounds. June 30, walked two miles. July 7, weight 127½ pounds. July 8, hardly coughed. July 19, very few bacilli,

temperature normal. August 17, trace of sputum, no bacilli. October 20, no dulness of the lung, murmur vesicular (confirmed by Dr. W. M. Thorne).

Case 7.—Miss N. R., aged 22, Oct. 2, 1895. Two cousins on the maternal side died of phthisis, it having been acquired from the father's side. Had the usual diseases of childhood. One year ago caught cold and has been coughing since then. Since April the cough has been worse and been attended by expectoration. The voice was clear formerly, at present it is husky.

Physical examination.—Ordinary weight 141 pounds, in July 124, on July 8, 133, September 24 145; large number of bacilli; spirometer 1700 c.c.; hemoglobin 60 per cent. (G.) Patient is a well developed, well nourished girl; cervical glands not enlarged; thorax long, broad, moderately arched, moderately deep; right side moves slightly less than the left, is flatter than the left; flatness of the right apex posteriorly to the second dorsal vertebra, of the left to the vertebral prominence; flatness of the right apex anteriorly to the first interspace, of the left in its uppermost portion; bronchial inspiration and expiration of both apices, few râles of the right; area of cardiac dulness normal, tones clear; liver and spleen not enlarged; weight 139 pounds. Injected 5 c.c. oxytuberculin; temperature normal. October 14, appetite much better, cough less. October 15, injected 10 c.c. October 20, weight 141½ pounds. November 7, weight 143½. November 16, no expectoration for a week. November 21, weight 144½. November 30, no expectoration in three weeks. December 7, no cough in twenty four hours. December 11, two sides of chest appear the same, no sinking of the supraclavicular fossæ, two sides move equally, no dulness of the lungs, pitch upon the right side is slightly higher, expiration slightly harder. December 12, 20 c.c. injected. January 20, no bacilli. March 17, 10 c.c. injected. March 24, raised sputum for the first time since the last note, contains a few bacilli. June 29, 10 c.c. injected. October 11, both sides move equally, no dulness of the lungs, murmur vesicular.

Case 8.—Miss S. D., age 22, April 2, 1896. Sister died of phthisis. Patient was well until two years ago, when she had a pulmonary hemorrhage. This was followed by a cough which persisted. Last Thanksgiving day had another severe hemorrhage; since then the cough has been worse and has been attended with expectoration, night sweats and dyspnea; Last Monday had another hemorrhage.

Physical examination.—Patient is fairly developed, moderately well nourished, pale, slightly cyanotic; cervical glands slightly enlarged; thorax long, moderately broad, fairly arched, moderately deep, slight scoliosis; left side moves less than the right; flatness of both apices posteriorly to the first dorsal vertebra; flatness of both apices anteriorly to the clavicle; bronchial inspiration and expiration of both apices with consonant râles; area of cardiac dulness normal, tones clear; liver and spleen not enlarged; spirometer 600 c.c.; hemoglobin 75 per cent. (G.); urine normal; bacilli in the sputum; average morning temperature 99.4, evening 100.5. April 13, weight 122 pounds. May, 1896, average morning temperature 98.5, evening 99. May 4, weight 120¾. May 28, cough and expectoration increased. June, 1896, average morning temperature 98.5, evening 99. June 9, no bacilli, feels stronger. June 11, has not expectorated for three days, weight 118¾. June 18, weight 119. June 28, weight 119, no cough or expectoration. July 1, is able to work, little cough, weight 119½. July 13, weight 117¾. July 21, working, feels well; 5 c.c. injected. July 28, weight 118; 10 c.c. injected. August 3, weight 117. August 17, spirometer 1900 c.c., hemoglobin 75 per cent.; slight depression of the left clavicular region, none of the right; two sides move equally on respiration; at the uppermost portion of the right apex the pitch is higher than the left, but no dulness can be detected; respiratory murmur vesicular, expiration harsher than at the left apex; weight 116¾. August 19, weight 118. August 27, no appetite, ordered strychnia .0027 gram three times a day. September 8, raised 1 c.c. mucus, the first in three days. November 2, no bacilli, has a little cough and expectoration. November 16, weight 113. December 1, 20 c.c. injected. Jan. 12, 1897, has pain in the chest. February 2, no expectoration for a month, weight 112. February 18, 10 c.c. injected. March 25, weight 113¼. April 2, no expectoration in three months. May 15, comes every other day. June 30, comes once a week. October 20, no expectoration for many months, two sides move equally, no dulness of the lung, murmur vesicular.

Case 9.—M. L., age 23, school teacher; Dec. 12, 1896. Mother and paternal uncle died of phthisis. Had the usual diseases of childhood. At 14 caught cold. Since then has coughed at intervals. Has shortness of breath on exertion and has had night sweats lately, period occurs every three weeks.

Usual weight 126 pounds, three months ago 117. Patient is well developed and fairly nourished; cervical glands very slightly enlarged; thorax long, moderately broad, moderately arched, moderately deep; flatness of both apices to the first dorsal vertebra, anteriorly of both to below the clavicle; bronchial respiration and consonant râles of both apices; throughout both lungs râles are heard; area of cardiac dulness to second rib, median line of the sternum to fifth, intercostal space to mammillary line; a murmur is heard at the apex that disappears during inspiration; liver and spleen not enlarged (examination confirmed by Professor Kerr, Professor Clinical Medicine, University of California, Medical Department); spirometer 1250; weight 117½; arytenoid cartilages slightly swollen; no bacilli in the sputum; temperature 99.8. Injected 10 c.c. January 9, injected 20 c.c. January 12, weight 119½. January 13, afternoon temperature 101. February 8, feels well, no cough, no expectoration; stop injection. April 10, has continued to improve, feels better than she has felt in two years, weight 121¼; two sides of chest move equally; no dulness of the lungs, murmur vesicular. October 4, feels well, has had a little inflammation in the throat below the surface of tonsil, scarified it and ordered peroxid, 1 to 6. October 22, weight 123¼. Patient looks and feels perfectly well, no dulness of the lungs, murmur vesicular. Dr. Barkan examined patient during the meeting and reported normal oral cavity. Epiglottitis and vocal chords, true and false, healthy in color and texture; arytenoid cartilage and interarytenoid space normal. Patient speaks clearly and attacks the tone well, no secretion.

Case 10.—Mrs. G. F. C., age 19; Aug. 10, 1897. Father had phthisis. Patient was well, as a girl, mature at 14, has not been strong since, coughed at that time and at times since. Coughed up blood several times last summer, the last time since then having been last week. Patient has been getting short of breath for the last three months. Weight last spring 130 pounds, January, 1897, 118, present weight 109. Patient is well developed, moderately nourished, pale; thorax long, moderately broad, fairly arched, moderately deep; both supra- and infra clavicular fossæ sunken; left side moves slightly less than the right; flatness of both apices posteriorly to the second dorsal vertebra, of left anteriorly to the second rib, of right anteriorly to below the clavicle; bronchial respiration of the right apex, amphoric respiration of the left apex with swishing râles; area of cardiac dulness normal, tones clear; liver and spleen not enlarged; moderately large number of bacilli; temperature morning 99.2, afternoon 102. Oxytuberculin was injected daily. August 16, cough less. August 19, feels better. August 21, stronger, cough and expectoration less, temperature normal. August 23, hemoglobin 65 per cent. (G.). August 28, cough very much less, expectoration less and feels stronger. August 30, feels very well. September 16, appetite better, moderate number of bacilli. October 16, appetite very good, weight 108¼. October 18, two sides move equally, dulness of both apices posteriorly to the first dorsal vertebra, right anteriorly to the clavicle, of the left to the two cm. below clavicle, bronchial respiration of the right apex, amphoric of the left, few râles. An examination made by the committee confirmed the very marked improvement that had been made in her case.

Case 11.—T. H. W., age 37; June 16, 1896. No heredity. In 1877 had chancroid; has had gonorrhea; been using cigarettes for thirty years; used alcohol to excess; has been coughing for a long time, this has grown worse during the past year, at times he has raised blood-tinged mucus; two weeks ago had a profuse hemorrhage and has had night sweats for many years. Patient is poorly developed, ily nourished, color moderately good, cervical glands not enlarged; thorax long, moderately broad and well arched, moderately deep; two sides move equally; dulness of both apices posteriorly to the third dorsal vertebra, right anteriorly to the second rib, of the left to and including the clavicle; loud bronchial respiration of both apices with consonant râles, mucus râles over other parts of the lungs; area of cardiac dulness normal, tones clear; liver 15 cm. Spirometer 3800 c.c., hemoglobin 70 per cent., urine contains pus; large number of bacilli in the sputum. June 18, Professor Kerr confirmed the examination; weight 145½ pounds; temperature morning 98, afternoon 101.6. Injections of oxytuberculin were instituted and very soon improvement occurred. June 26 it was noted that the cough was better than it had been in months, and by July 5 the temperature became normal and has remained so to the present. August 10, a few bacilli were found in the sputum. September 23, the patient expectorated a little blood, but otherwise no increase of unpleasant symptoms, so that by December 17 only 4 c.c. of jelly-like mucus was expectorated in the twenty four hours. December 29, no bacilli could be found in the sputum. January 19, patient complained of rheumatism

in the shoulders, for which salicylate of soda and hot baths were used. By January 30 he was entirely recovered from this slight ailment. March 2, a very small number of bacilli were found in the sputum. March 18 he caught cold but had no rise of temperature, coughed up a very small amount of blood, in which bacilli were found. April 2, no bacilli were found in the sputum, nor have any been found since that time. At the present time the patient is perfectly well and strong, the most careful examination made fails to reveal the slightest sign of the disease of the lung, either to me or any of the six other physicians who have examined him.

Case 12.—Miss G. P., age 18. Has been having cough for one year with profuse expectoration, night sweats and hemorrhages. First presented herself July 3, 1896. Weight 104½ pounds. Patient is poorly developed, moderately well nourished, very pale; thorax long, moderately broad, flat, shallow; left side decidedly flatter than the right, moves very little on respiration; dullness on right side to first dorsal vertebra, anteriorly to and including the clavicle; dullness of the left apex posteriorly to the sixth dorsal vertebra, anteriorly to the second rib; bronchial respiration of the right apex and amphoric respiration of the left; temperature morning 102.5, afternoon 105. Treatment with injections of oxytuberculin was begun September 30. Weight 122¾ pounds. Temperature after October 1 normal with an occasional rise of temperature to 101. November 4, weight 125¾. November 14, very few bacilli present. November 21, weight 127½. March 4, patient took cold and went to the country, returning on the 25th in a very much worse condition than she had been since she first presented herself, weight being 112¾ and the temperature ranging as high as 102. Treatment of oxytuberculin was again instituted and improvement began. April 9 a moderate number of bacilli tuberculosis were found in the sputum. By April 24 the temperature became normal and has remained so since. When presented to the committee it was found that the left side of the thorax was slightly flatter than the right. The left side moves slightly less than the right in the upper part. No dullness whatsoever of the right lung. Respiration vesicular. In the left lung dullness was found posteriorly to the first dorsal vertebra and anteriorly to the second rib, amphoric respiration was heard in this region, but very few rales. Her weight was 125 pounds, and no bacilli were found in the sputum.

Case 13.—C. H. W. Was sent to me Jan. 22, 1897, from the Throat Clinic of the Cooper Medical College with the diagnosis of acute tuberculosis laryngitis, with the following report:

Left cord does not move. Cartilaginous portion narrow, membranous portion rounded and pearly white. Left arytenoid cartilage somewhat edematous, edema of the arytenoid having much increased in the last few days.

Patient was found to be moderately developed, poorly nourished, somewhat cyanotic, with dullness of the right apex to the third dorsal vertebra, of the left to the second; anteriorly of the right to the second rib, of the left to the first intercostal space. Bronchial respiration and rales of both apices, amphoric respiration below the right clavicular region; large number of bacilli in the sputum. Temperature, afternoon, 101.2; weight 129½ pounds.

Patient had profuse expectorations, was dyspneic and had numerous bacilli in sputum.

Administration of oxytuberculin was instituted January 22, and a few days later he reported that he slept better and felt better; temperature, P.M., 100.4. From that time to the present the temperature has never risen above the normal. February 2, he had a hemorrhage. February 13, the laryngologic clinic reported the larynx better, and from that time on a continued improvement in the condition of the larynx occurred. October 21, a large number of bacilli were found in the sputum. Dullness of the left apex was found to the first dorsal vertebra; bronchial respiration; no dullness of the right was found. There was very little cough, the expectoration being only one-half as much as it had been when he first presented himself. Patient had the rosy appearance of health and had no shortness of breath. His weight, however, was only 128½ pounds.

An examination by Professor Barkan made at the time of the meeting gave the following report: Epiglottis healthy, true and false vocal cords of good color and texture. Left cord does not move as well as right toward the medium line of phonation. Left arytenoid slightly thickened. Voice clear.

Case 14.—J. P. A.; was admitted to the City and County Hospital July 15, with the following history: He had been well with the exception of stomach and bladder trouble until one week ago, when he suddenly became short of breath. His legs began to swell and he passed bloody urine for the same length of time. He was found to be cyanotic and dyspneic, with general anasarca. Dullness of the right apex was to the second dorsal vertebra; bronchial respiration. The sputum

contained bacilli of tuberculosis in large numbers. In the bloody urine bacilli tuberculosis and a moderate quantity of albumin were found.

The case was diagnosed as acute miliary tuberculosis, but so little expectation of accomplishing anything in the case was felt that an examination of the blood for bacilli tuberculosis was, unfortunately, not made. Injections of oxytuberculin were begun and the patient rapidly improved, though high fever continued for a long time, but with the last two weeks has entirely disappeared. August 17 the patient was able to walk around the wards, and the urine was no longer bloody, nor has it been so at any time since. August 28, his weight was 133 pounds. September 25, his weight was 135. October 2, his weight was 138. October 6, after much search a few bacilli could be found in the sputum and in the urine only a trace of albumin, but no bacilli. October 19, patient became attacked with sciatica, for which he was blistered and confined to his bed. His weight on October 23 was reduced to 134 pounds.

In this case the gradual improvement had been observed by the class of medical students at Cooper Medical College, who saw him from time to time in the wards.

In the subjoined table sixteen cases that had been treated early in the course of the investigations with oxytuberculin heated only thirty hours and giving less favorable results have been omitted.

FOURTH STAGE.

No	Name.	Days Treated.	Bacilli.		Cured.	Much Improved.	Slightly Improved.	Unchanged.	Worse.	Dead.

Total	70	16	36	6	6	1	5

When in this table it is stated that a patient has become well I mean that bacilli tuberculosis have been absent at repeated examinations running over a long period of time, that the patient feels well and strong, and above all that physical examination of the chest does not reveal any signs of the disease. Any case not filling all of these requirements has provisionally been classed among those who have improved. It has been my purpose to place the most stringent demands upon the treatment.

In administering the remedy needles not less than one-half inch in length have been used so that the oxytuberculin might be injected well under the skin.

443 Geary Street.

A CLINICAL STUDY OF TUBERCULOUS CASES TREATED WITH THE NEW ANTIPHTHISIC SERUM T. R.

(FORMULA OF FISCH.)

BY A. MANSFIELD HOLMES, A.M., M.D.

DENVER, COLO.

Serum therapy has been so extensively used that scarcely a well informed person can be found who does not entertain an opinion either for or against it.

However, the principles underlying this method of medication, the nature of toxins and antitoxins, their mode of preparation, administration and action are very imperfectly understood.

A great variety of opinions are held both by the profession and the laity concerning the effects of this treatment in tuberculosis. Many of these opinions however are based upon no firmer foundation than that of prejudice.

For some time past I have used with my tuberculous patients, a serum prepared by immunizing the horse with Koch's old tuberculin. I have obtained from

this product very satisfactory results in several cases.

Soon after the introduction of Koch's new "tuberculin T. R.," I tested its utility on a few well selected cases of tuberculosis. A short time later I was informed by Dr. Carl Fisch of St. Louis that he was immunizing horses with the new "tuberculin T. R.," hoping to be able to furnish a serum with more potent antitoxic properties than those possessed by the old serum. This at once appealed to me as being the most rational therapeutic agent yet proposed for the treatment of tuberculosis.

As is well known, Koch's old tuberculin contains only the toxins secreted by the bacilli. If the use of the old tuberculin on the horse could produce a serum capable of bringing about the satisfactory results which I had obtained in the cases tested by it, I felt very confident that the new "tuberculin T. R."—being a more complex toxin, containing not only the toxins secreted by the bacilli, but also those contained in the tissues of the bacilli themselves—if used to immunize the horse would produce a more complex antitoxin, which would not only be an antidote for the toxins secreted by the bacilli, but also for those contained within the substance of the germs; in other words, possessing both antitoxic and bactericidal properties.

At this time I was honored by a request from Dr. Fisch to test the new product upon a series of tuberculous cases. I accepted the invitation and commenced the work as soon as the horses were considered immunized and Dr. Fisch had tested the serum upon animals. The following report therefore is the first account giving the results obtained with this serum upon patients.

Before proceeding with the report it will probably be well to clearly define the principles underlying immunization; and, furthermore, to come to a clearer understanding of the rôle played by toxins and antitoxins in bringing about this condition.

It is the nature of toxins when administered to an animal to stimulate the organism to a greater production of antitoxins. This is known as active immunization.

On the other hand, the antitoxins produced by a healthy animal may be administered to an organism possessing a diminished supply of these antitoxins. The result thus obtained is known as passive immunization.

Moreover, since every living organism is endowed with the ability to generate protective substances known as antitoxins; yet this ability is possessed in variable degrees by different individuals, according as they are in a normal or diseased state, or according to the species to which they belong.

Therefore if the antitoxin supply of any organism becomes diminished by disease, either in quantity or quality, it has already been shown that an effort may be made to overcome this deficiency by one or the other of the foregoing methods of bringing about artificial immunization.

By the active method a toxin is used for the purpose of stimulating the organism to a greater production of antitoxins. But it will be readily seen that in weak persons this method would be simply an effort to increase the functional activity of an organism that is already overworked.

While, on the other hand, by administering antitoxins produced by a healthy or immunized animal to one deficient in these products the weaker organism

will be temporarily supplied with that which it is not able to prepare for itself; and during this period instead of being stimulated to a still greater activity it will have an opportunity to rest and recuperate.

This is exactly the result which I have observed by administering the "antiphthisic serum T. R." to tuberculous patients.

The following is the report of my first ten cases treated by this new serum:

Case 1.—Mrs. N., age 30, native of Kentucky.

Family history.—Sister died of tuberculosis at 20, sick two years; four months later a brother died of tuberculosis at 32, sick five years; the mother having nursed the son and daughter through their sickness showed evidence of tuberculosis a short time before their death, and died of the disease eighteen months later. Also, one aunt had tuberculosis.

Personal history.—Present trouble began four years ago. Former weight 137, lost gradually until her weight was reduced to 80, slowly improved until she reached 103 pounds. In June, 1897, a cough and expectoration commenced and she came to Colorado.

Physical condition.—Upon examination one month after arriving in Denver, I found a small area of dullness over the upper lobe of left lung with moist râles in the apex on forced inspiration; frequent pains in the lung; cough and morning expectorations; afternoon temperature $99\frac{1}{2}$; weight 110. Slept poorly, appetite moderate; weak, easily exhausted and very susceptible to cold.

Treatment.—I commenced treatment with Koch's new "tuberculin T. R." on August 6, continued for two weeks, increasing the dose from $\frac{1}{500}$ mg. to $\frac{150}{500}$ mg. At the expiration of two weeks weight reduced from 110 to $106\frac{1}{2}$ pounds. A marked reaction developed under an increasing dose in the form of a distinct chill. August 25 treatment was changed to "antiphthisic serum T. R.," commencing with $\frac{1}{3}$ c.c. The dose was slowly increased to 1 c.c. At the end of one week under the serum she had gained two and one-half pounds. Felt better and stronger and slept better.

Reaction.—Patient experienced the first reaction on the ninth day in the form of a tired feeling with an inclination to sleep most of the time. During second week cough and expectoration ceased, appetite improved, slept better and gained two pounds. Temperature normal at the end of third week. At the expiration of six weeks of the serum treatment patient felt a constant improvement. The pain had disappeared from the lung, cough and expectoration had ceased, râles had disappeared and there was a gain of seven and one-half pounds. Patient much stronger, riding a bicycle, and was much better than for three years. Patient discharged cured. Treated with Koch's old tuberculin without a reaction. Dose never exceeded 1 c.c. Temperature never more than one degree above, but more frequently subnormal. One month after stopping treatment patient had gained two pounds and continued to improve.

BLOOD STUDY: TABLE I.¹

Date, 1897.	Differential Percentages.				
	S. L.	L. L.	Trans.	Phag.	Eos.
August 13	20	8	2	68	2
August 21	24	13	3	53	7
September 20	32	7	0	58	3
October 4	34	6	1	56	2
November 5	27	10	0	61	2

August 6-23 gave "tuberculin T. R." August 25 to October 4 gave "antiphthisic serum T. R." Last blood examination made November 5, one month after stopping treatment.

Results.—Small lymphocytes almost double in number, also an increase in the number of eosinophilous cells and decrease in amount of cell disintegration. One month after stopping treatment the relative percentages adjusted themselves to almost normal.

Case 2.—Mr. H., age 22, single, nativity, New York.

Family history.—Father died of tuberculosis.

Personal history.—Has always been delicate. Had typhoid fever two years ago. Has been a close student for several years. Present trouble commenced last spring while in college. Began with a severe cold, pain in left lung, cough and expectoration, loss of weight and strength. Came to Colorado

in June through the advice of his physician. Remained in the mountains during the summer, sleeping in a tent, living in the open air, nourished by the best of food, but under no treatment. Gained in weight, appetite improved, and in many ways felt better, but the cough and expectoration continued, and occasionally a pain in the left lung.

Physical condition.—Patient consulted me September 4. A physical examination revealed slight dullness over upper lobe of left lung, with moderate localization infiltration, and a few fine râles on forced inspiration. Temperature 98, pulse 84, weight 143 pounds.

Treatment.—Commenced the "antiphthisic serum T. R." beginning with $\frac{1}{2}$ c.c. On third day increased to $\frac{2}{3}$ c.c. Continued the latter dose for five days. During the third and fourth days temperature rose to 99, but soon dropped to normal and remained so during the month.

Reaction.—The first evidence of reaction developed at close of first week. The left axillary glands became tender and moderately enlarged, and left shoulder stiff. Patient felt tired and experienced a tendency to sleep much of the time. These effects disappeared after the third day. During the reaction the appetite was not impaired. Immediately after the reaction appeared, the cough and expectoration became less. End of second week cough and expectoration had ceased. At the close of first month patient had gained three pounds and felt stronger each day. Pain disappeared from lung, chest expansion had increased three-fourths of an inch, râles had disappeared and dull spot was clearing. Patient discharged with no evidence of the disease remaining. During the month no treatment used except the serum and lung gymnastics. Maximum dose 1 c.c. A second reaction did not appear.

BLOOD STUDY: TABLE II.

Date, 1897.	Differential Percentages.				
	S. L.	L. L.	Trans.	Phag.	Eos.
September 11	17	5	1	74	3
September 18	24	9	0	60	7
September 25	27	8	0	60	5
October 2	27	9	0	60	4

Case 3.—Miss S., aged 34; nativity, New York.

Family history.—Mother died of tuberculosis at 64, sick six months; one sister at 20 sick six months; five cousins on mother's side between 20 and 30, and one aunt at 60.

Personal history.—Present trouble began four years ago. Had pleurisy in right side. Cough soon developed, accompanied by almost constant pain in right lung. Soon afterward patient came to Colorado. Former weight 114 pounds, weight on arriving in Colorado three years ago 93 pounds. Improved slightly in Colorado, but cough and pain in right lung persistently increased. Continuing very susceptible to climatic changes, and did not gain strength.

Physical condition.—Examination August 15. No râles detected in either lung. Dullness and slight consolidation over upper portion of right lung, with impaired breathing. Temperature $99\frac{1}{2}$; pulse 92. Weight 103 pounds. In connection with this case there was also well marked acne involving the face and back, which had existed since puberty without yielding to treatment.

Treatment.—Began "antiphthisic serum T. R." September 11, and continued two months. Initial dose $\frac{1}{4}$ c.c. At the end of second week was giving 1 c.c. Temperature during first week persistently remained one degree above normal, but fell to normal during second week.

Reaction.—The first reaction developed early in the second week. Axillary glands enlarged and tender on both sides. Face flushed in evening after taking the serum. Felt tired and inclined to sleep much of the time. For a few days while the reaction was most marked, shoulders were stiff much the same as after taking a cold. Following the reaction of the second week improvement was marked; slept better; appetite improved, cough and expectoration diminished; looked and felt better and strength increased. Cough ceased entirely at end of second week, and pains in lung disappeared. Appetite greatly improved. Also an unexpected evidence of improvement developed. At close of the second week the acne which had been so persistent on face and back commenced to disappear. By the end of third week the face was entirely clear and there has been no return. Patient continued to feel better and gained in strength to the close of the treatment at the end of two months; feeling better than at any time since commencement of her trouble. Lost three pounds during first month which were regained during second month. No treatment used except serum. One month after stopping treatment patient feeling well with no evidence of the disease to be found.

¹ The following classification of leucocytes is used in this study with the approximate normal percentages for each: Small lymphocytes 26; large lymphocytes 8; transitional 1; phagocytes 64; eosinophils 1. The percentages in the tables represent an average of 500 leucocytes.

BLOOD STUDY: TABLE III.

Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.
August 15	25	5	0	68	1
November 6	33	6	0	57	4
November 13.	29	5	0	63	3
November 18.	30	5	0	61	4

Case 4.—Mr. M., age 32, nativity, Ohio.

Family history.—Father died of tuberculosis at 45, sick three years. Also father's mother at 30, sick six months.

Personal history.—Present trouble commenced one year ago. Had severe pneumonia involving left lung. A cough existed previous to the pneumonia and increased afterward, accompanied by morning expectoration. Very susceptible to climatic changes. Former weight 145, present weight 133.

Physical condition.—Small dull area over central portion of left lung. Pain on pressure, also distinct rough breathing on forced inspiration, but no râles detected. No bacilli, temperature 99.4, pulse 98. This case can not be said to be one of active tuberculosis. But the family and personal histories accompanied by his physical condition justified the suspicion of a strong tuberculous predisposition which was confirmed by a blood study. I advised the patient to try the "antiphthisic serum T. R.," for the purpose of bringing about artificial immunization before he had advanced to the so-called "active stage" of the disease.

Treatment.—Commenced the serum October 16, beginning with $\frac{1}{4}$ c.c. Increased the dose from $\frac{1}{4}$ c.c. to $\frac{1}{2}$ c.c. during first week with no reaction. Gained two pounds. Temperature reduced to normal. During second week dose increased to 1 c. c. Slight reaction experienced. During third and fourth weeks gave a daily dose of 2 c.c. Improvement marked. Temperature dropped to normal or subnormal. At the end of one month patient is in an excellent condition, feeling better, much stronger; cough and expectoration ceased, pain left the lung, appetite improved, gained five pounds. Patient discharged feeling better than for years.

BLOOD STUDY: TABLE IV.

Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.
October 14.	21	5	0	67	7
November 6	24	4	1	64	7
November 17.	25	4	0	66	5

Case 5.—Miss R.; nativity, Massachusetts.

Family history.—Maternal uncle died of tuberculosis at 30, sick three months. Maternal aunt at 28, sick less than three months. Paternal grandmother has intestinal tuberculosis. Father has intestinal troubles.

Personal history.—Has always been delicate. Present trouble commenced two years ago in the form of a severe bowel trouble, which has not yielded to treatment. Very feeble endurance. Takes cold quickly, which always manifests itself in an increase of the bowel trouble. Patient also has a severe form of acne.

Physical condition.—Lungs normal. No cough or expectoration. Tenderness over bowels with more or less tympanitis. Temperature 99, pulse 82, weight 116. I suspected intestinal tuberculosis and advised the "antiphthisic serum T. R."

Treatment.—Commenced October 13, with $\frac{1}{4}$ c.c., increasing the dose until 2 c.c. were given at the end of fourth week. At the end of first week temperature was reduced to normal, and during a further treatment of six weeks it fluctuated between normal and one degree below.

Reaction.—At close of first week reaction was experienced in the form of a tenderness and swelling of axillary glands, stiffness in shoulders, a tired feeling and a tendency to sleep. The acne also showed improvement at the end of the first week, and at the close of six weeks had almost disappeared. The general condition of patient improved as the treatment progressed. Bowel trouble gradually improving, weight increased five pounds. Patient stronger and less susceptible to climatic changes, appetite improved, gained in strength and in every way better than for two years. Treatment continued.

BLOOD STUDY: TABLE V.

Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.

November 8.	24	7	1	65	3
November 13.	19	3	1	71	6
November 20.	21	7	1	61	10

Case 6.—Mrs. F., age 24; nativity, Indiana.

Family history.—Maternal and paternal grandmothers died of tuberculosis, also a nephew at 19, sick one year, and all cousins on both sides at ages ranging between 17 and 21.

Personal history.—Present trouble developed after an attack of gripe. Fever, cough and expectoration followed. Had two slight hemorrhages. Bacilli were present. Has had cardiac weakness, occasional albuminuria, asthma and chronic bronchitis. Has spent most of her time in Colorado for several years with very little improvement.

Physical condition.—No actual lung lesion found, but general state of health feeble. Troublesome cough with very little expectoration. Much pain in lungs. Takes cold very easily, accompanied by an increase in the foregoing symptoms. Bacilli have disappeared from sputum since coming to Colorado.

Treatment.—Patient placed under the "T. R. serum" October 19, commencing with $\frac{1}{4}$ c.c. A slight reaction developed from the first dose. Dose was slowly increased. At the end of first week was giving $\frac{1}{2}$ c.c. No severe reaction experienced, but several hours after giving the serum, patient felt tired and sleepy accompanied by marked flushing of the face. Invariably felt better after each reaction. End of fourth week appetite improved, slept better, gained in weight, felt better, and cough had ceased. Temperature continued throughout the month at normal or subnormal. Patient gradually improving. Feels better than for six months. Takes 1 c.c. with little reaction. Treatment continued.

BLOOD STUDY: TABLE VI.

Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.
September 29.	19	12	1	66	2
October 19.	30	9	1	57	3
November 13.	29	11	1	55	4

Case 7.—Mr. C., attorney, aged 28, nativity Nova Scotia.

Family history.—Father died of tuberculosis at 39, sick eleven years. All cousins on the father's side died of the disease between 18 and 26.

Personal history.—Present trouble commenced with gripe in February, 1895. Previous health good but had been overworking. Cough, expectoration and night sweats commenced at this time. Returned to office after five weeks, but cough and expectoration continued. Aphonia developed and continued until the following July. During July had two hemorrhages. Examination of sputum revealed bacilli. Weight reduced from 148 to 136 pounds: came to Colorado in October, 1895. Has gained since coming to Colorado. Aphonia has disappeared, strength increased and gained in weight, but cough and expectoration continued, and often tinged with blood.

Physical condition.—Patient was examined November 1: fine râles detected in upper lobe of right lung, over which was a small area of dullness; cough troublesome, expectoration moderate in amount; bacilli present.

Treatment.—Patient commenced the "antiphthisic serum T. R." November 3. During first week increased the dose from $\frac{1}{4}$ c.c. to $\frac{1}{2}$ c.c. The first reaction developed on fourth day. Felt sleepy all afternoon after taking the serum. During the remainder of the week slept the greater part of the time. By the end of the first week appetite much better than for years: felt stronger. During second week dose increased from $\frac{1}{2}$ c.c. to 1 c.c. Early in the second week the axillary glands became tender and slightly enlarged; felt tired, weak and sleepy. This reaction soon disappeared and patient felt much better and stronger. During third week dose increased to $1\frac{1}{2}$ c.c., very little reaction experienced: cough no less, but easier, feeling better each day; sleeping better and much stronger. Gained two pounds: pain in lungs diminishing. Treatment continued.

BLOOD STUDY: TABLE VII.

Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.
November 1.	17	8	2	69	4
November 11.	20	14	0	58	8
November 18.	20	2	1	69	8
November 23.	22	12	0	58	8

November 3 commenced the serum. Blood examination revealed the distinct characteristics of incipient tuberculosis. November 11, revealed marked improvement: the small lymphocytes showing an increase and the eosinophilous cells doubling in number.

Case 8.—Mr. H., aged 42, married, nativity Ohio.

Family history.—Two uncles and one cousin on father's side died of tuberculosis.

Personal history.—Engaged in educational work for years. A hard worker, but enjoyed good health until three years

ago. For years had taken cold readily, always followed with a cough, expectoration and soreness in lungs. During spring of 1896 over-worked and health commenced to fail. Came to Colorado and consulted me for a diagnosis. Lungs revealed no evidence of tuberculosis: a blood study, however, revealed much cell disintegration and marked alteration in the relative percentages of the various types of leucocytes. I gave a diagnosis of marked tuberculous predisposition and advised patient to rest for one year and remain in Colorado. The case was reported as No. 34 in my article on "The Diagnosis of Tuberculosis from the Morphology of the Blood" (*Med. Record*, Oct. 5, 1896). Patient declined the advice given and returned East the last of August and commenced his school work. Cough and expectoration commenced the last of December; lost weight and strength and in March, 1897, broke completely down with what physicians called "pleuropneumonia." Confined to his room five weeks. Cough, expectoration and high fever continued. Came to Colorado the second time last July.

Physical examination.—Both lungs very seriously involved; bacilli abundant; marked variation in daily temperature varying from from 102 $\frac{1}{2}$ to 104 $\frac{1}{2}$, pulse 110. Former weight 138, present weight 111. Cough troublesome, expectoration profuse, night sweats, diarrhea, extreme dyspnea, poor appetite and sleep.

Treatment.—Gave "tuberculin T. R." for one month, increasing dose from 1 $\frac{1}{2}$ mg. to 350 $\frac{1}{2}$ mg., with very little if any improvement during the month. Gave "antiphthisic serum T. R." during the second month. Increasing the dose from $\frac{1}{2}$ c.c. to 3 c.c.; slight improvement in all symptoms except temperature and pulse; cough and expectoration less, appetite improved a little and slept better, but these were only for a short duration. During the last week of treatment I used "antistreptococcus serum" (Fisch) in connection with the "antiphthisic serum T. R.," giving each on alternate days. After the first dose of the "antistreptococcus serum" the temperature fell from 101 $\frac{3}{4}$ to 99 $\frac{1}{4}$. For three days the temperature remained between 99 and 100, being the lowest point reached for more than six months. Patient became gradually weaker, pulse more rapid and appetite less. During the two months of careful treatment patient rapidly failed. Treatment stopped. Patient returned East; lived one month.

Case 9.—Mrs. D., age 37; nativity, Pennsylvania.

Family history.—Very good. No tuberculosis on either side.

Personal history.—Present trouble began about two years ago. Patient lived in a double house, a tuberculous patient living in the adjoining apartment. Our patient received daily visits from her neighbor who was careless about her sputum. Expectoring profusely on floors and sidewalk. Our patient in sweeping her apartments inhaled the dust, not knowing the danger from the dry sputum.

At this time she was exhausted with other troubles and very susceptible to the germ. The above influences existed for five months before she noticed any trouble. It first developed by a sensation of a foreign substance in her throat. This increased and a cough soon developed, followed by expectoration. Six months ago aphonia developed and one month later she came to Colorado.

Physical condition.—Left lung very seriously involved; cavity and coarse and fine râles throughout the lung. Cough excessive, expectoration profuse, bacilli abundant. Poor appetite, insomnia, aphonia, diarrhea and amenorrhea. Temperature 101.8 degrees, pulse 120, and scarcely able to go to meals. Former weight 139; present weight 114.

Treatment.—Commenced July 29 with Koch's "tuberculin T. R.," from 1 $\frac{1}{2}$ mg. to $\frac{1}{2}$ mg. at the end of three weeks. During this treatment the temperature was reduced to 99 and pulse to 104. Bowel trouble slightly better, voice and appetite improved and slept better, but cough and expectoration had increased and night sweats appeared. August 25 changed to "antiphthisic serum T. R." At the end of three weeks patient felt much better and stronger, appetite improving, slept better, night sweats ceased and gained two pounds. But cough and expectoration had not improved and temperature was fluctuating between 98.4 and 100.6; bacilli abundant. I then resolved to use "antistreptococcus serum" in connection with the

"antiphthisic serum T. R.," giving each on alternate days, increasing the dose gradually until at the end of two weeks more, 3 c.c. of each were being administered. Patient felt no bad effects from the increased dose except slight rheumatic pains in joints. Appetite and sleep both increased. Patient felt better and was gaining in strength. Coughed less at night. At this time a despondent mood came over patient and she stopped all treatment. Omitted treatment almost one month. During this time all symptoms increased and upon re-examination I found the left lung involved throughout and the trouble extending to the other lung. Temperature 101, pulse 120, patient weaker and evidently had lost ground. Patient commenced treatment again, taking the "serum," but very irregularly, omitting it almost half of the time. On November 19 there was no evidence of actual improvement. Cough and expectoration no less, temperature and pulse somewhat less, appetite and sleep better. Treatment continued. Subjective symptoms apparently better.

BLOOD STUDY: TABLE IX.
Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.
July 6.	10	9	1	78	2
August 5.	13	6	0	79	2
September 22.	15	9	0	72	4
November 14.	10	10	1	77	2
November 22.	14	6	1	75	4

July 29 to August 23 used "tuberculin T. R." August 25 to September 17 used "antiphthisic serum T. R." August 17 to 28 used "antiphthisic serum T. R." and "antistreptococcus serum on alternate days." September 28 to November 14 omitted treatment. November 14 commenced "antiphthisic serum T. R." again.

Case 10.—Mr. C., age 25, single, nativity Pennsylvania.

Family history.—Maternal grandmother died of tuberculosis. All of her sisters died of tuberculosis. Mother died of tuberculosis at 47; sick four years. Confined to her room one year before her death.

Personal history.—Has never been strong. First evidence of present trouble commenced six years ago. Was almost constant attendant of his mother during the last year of her sickness and slept in the same room. His trouble commenced three months after commencing to care for his mother and nine months before her death. Commenced by taking a severe cold, in mid-summer, without any apparent cause. Cough, expectoration and night sweats soon followed. Former weight 135. Has had several slight hemorrhages. Came to Colorado three years ago.

Physical condition.—Physical examination revealed distinct râles over all parts of right lung. Left lung not involved. Cough troublesome, expectoration moderate, bacilli abundant, poor sleep, very poor appetite, temperature normal or slightly above, weight 115 $\frac{1}{2}$.

Treatment.—Commenced "antiphthisic serum T. R.," September 23, with initial dose of 0.5 c.c. Reaction: More tired and stupid than usual. September 24 gave 0.75 c.c. Reaction: Back around puncture became swollen and painful. Axillary glands tender on both sides. Rheumatic pains in both hands. Cough diminishing. Temperature 99. September 26 gave 0.5 c.c. Axillary glands tender and swollen. Tenderness in joints. Slept six hours in the afternoon after taking serum. September 27 28 gave 0.5 c.c. Same reaction continuing with no new developments. September 29 omitted the serum.

Second week.—September 30. Temperature normal. Axillary glands less painful. Appetite improving. Felt better in every way. Gave 0.5 c.c. Reaction well marked. Slight rheumatic pains in joints. Felt chilly in the evening. Axillary glands less sensitive. During the remainder of the second week reduced the dose to 0.25 c.c. and gave it on alternate days. Patient recognized a marked improvement, slept better and appetite improved. Temperature normal. Circulation better. Reaction less, marked improvement, except considerable infiltration around punctures. Lost two pounds.

Third week.—Same dose continued. Respiration deeper, circulation stronger. Appetite slowly improving. Did not tire so easily, slept better, felt stronger, gained two pounds. Temperature normal.

Fourth week.—Same dose continued, followed by a slight improvement.

Fifth week.—Commenced daily treatments of 0.25 c.c. Very little reaction except felt tired, with a tendency to sleep. Cough much improved. In every way felt better.

Sixth week.—Increased the daily dose to 0.5 c.c. A slight instantaneous reaction followed the first injection of 0.5 c.c. The punctures continued to produce distinct infiltration and

tenderness. Toward the end of sixth week increased the dose to 0.75 c.c. Patient slept all night and awoke hungry. Temperature continued normal notwithstanding the injection set up marked inflammation around the punctures. Patient looking better and feeling stronger. The results were so satisfactory from the increased dose that on November 2 I increased it to 1 c.c. This was followed by excellent results, except that it produced marked inflammation. Each injection not only setting up a distinct swelling and tenderness at the seat of puncture, but also increasing the inflammation around the previous punctures on the opposite side of the back. The first injection of 1 c.c. (November 2) set up such acute inflammation that it quickly developed into a small abscess. Consequently during the seventh week the serum was discontinued. On November 7 the abscess was opened. Except for the pain caused by the abscess the symptoms were very encouraging. During this week the cough and expectoration were much less than at any other time during the previous treatment.

Eighth week.—Patient much improved and insisted on beginning the serum again. Cough almost ceased except in the morning on arising, also very little expectoration. Encouraged by the marked improvement I began the serum again (November 11) with 0.25 c.c. Slowly increased the dose each day until 1 c.c. was reached at the end of the eighth week with no unpleasant reaction. Symptoms rapidly improving. Patient tolerating the injection much better than before the abscess formed. Pulse reduced from 108 to 90. Temperature normal. I commenced this case knowing it to be a desperate one. The patient had very little hope of being benefited. It has required careful study but the results have more than rewarded me for the care and anxiety devoted to it. The blood study has been unusually interesting. Additional treatment used in Cases 8, 9 and 10: Gude's peptomangan and Fairchild's panopepton. Careful lung gymnastics used in all cases. Case continued under observation.

BLOOD STUDY: TABLE X.

Differential Percentages.

Date, 1897.	S. L.	L. L.	Trans.	Phag.	Eos.
April 30	14	9	1	75	1
September 23	16	9	1	71	3
October 9	17	9	1	66	7
November 3	10	7	1	71	11

November 7	17	6	0	75	2
November 13	17	6	0	72	5
November 20	17	7	0	67	9

September 23, commenced "antiphthisic serum T. R." October 9, improvement commencing. November 3, inflammatory leucocytosis. November 6, abscess forming. November 7, after opening the abscess. November 13, improving. November 20, much better, stronger and coughs less.

Blood Study.—The blood study made in the foregoing cases has constituted no small part of the labor connected with this research. The interesting blood changes observed during the progress of the treatment is a strong proof of the curative effect produced by the serum. The variation in the differential count as given in the tables were by no means the only characteristics observed in the blood. There are also many grades of cell disintegration, as well as many grades of imperfect cell development in such blood. But it is not my purpose at this time to discuss blood appearances in tuberculosis, since I have already attempted this in a former paper.² I have however used this means of study to aid in forming a more accurate conception of the true condition of the patients when beginning the serum and to aid in following the progress of the cases while under the treatment. The blood study in these cases shows conclusively that distinct and uniform blood changes progressively develop as the disease advances. While on the other hand equally as important changes develop as the cases return to the normal state. I have observed that in those cases in which improvement was taking place the first evidence was detected in the blood. These changes are as follows and are

shown in the foregoing tables: *a*, an increase in the percentage of young cells or small lymphocytes; *b*, a decrease in the percentage of phagocytes; *c*, an increase in the percentage of eosinophilous cells; *d*, a decrease in the amount of cell disintegration.

On the other hand, when the disease was advancing the foregoing symptoms were reversed, as seen in Case 8. Therefore, this study demonstrates that the cases treated with the serum show that the deterioration of the blood is diminished and that there is an added stimulus in the direction of increasing cell genesis and constructive cell metabolism. In other words, the two conditions which universally increase with the advance of the disease are observed to diminish; and with beginning convalescence they show a tendency to return to the normal.

Indispensable factors.—The skill required for the proper preparation and administration of serum is scarcely yet appreciated. Serious consequences may result unless the products are prepared according to accurate scientific principles, by those who care more for a reputation of conscientious work than for commercial profit. While on the other hand the improper administration of a pure serum may bring about results which may unjustly be attributed to the serum. The greatest care in the administration of an impure or decomposed serum will not prevent the development of unpleasant results. Hence, for satisfactory results in serum therapy there are two indispensable factors: Pure products and cautious administration.

Physiologic effects.—I have experienced not a little satisfaction in the fact that there have been no unpleasant or dangerous results from the administration of this serum. It, however, produces reactions which are as characteristic of the physiologic effects as are obtained from the use of quinin or any other therapeutic agent, and if carefully and properly administered I have found no occasion for alarm.

Symptoms of slow reaction.—An increase in the dose brings about physiologic effects which are not uniform in all cases. These may briefly be enumerated as follows: A tired sensation; a desire to sleep much of the time; rheumatic pains involving the joints; tenderness and swelling of axillary glands; chilly sensations, which generally appear several hours after receiving the injection; inflammation at seat of puncture which usually is slight and ceases after first or second week; an erythema, which is not severe and soon disappears; a flushing of the face after the injections, sometimes immediately, but more frequently several hours later; occasionally a tingling sensation is experienced over the surface of the body several hours after taking the injection, and when it occurs it is generally early in the treatment or at a time when the dose is being increased. Headache seldom or never occurs.

Instantaneous reaction. A sudden reaction sometimes occurs after an injection of any serum. It is probably due to a too sudden and forcible injection of the fluid, especially when the point of the needle terminates in dense and non-elastic tissues.

The needle produces more or less injury to capillaries or veins. And since a compressed liquid naturally tends to escape through channels of least resistance, the pressure of the tissues upon the serum directly forces it into the blood current through the rupture made in the blood vessels. When this occurs an instantaneous reaction of more or less intensity may be produced. This varies somewhat in different

² Medical Record, Sept. 5, 1896, March 13, 1897. Journal of the American Medical Association, Oct. 23, 1897.

persons and at first may cause alarm, but soon subsides without leaving any deleterious results. When the serum is thus forced directly into the blood stream the full physiologic effect is suddenly experienced. While on the other hand if the serum is injected slowly into the loose tissues, absorption takes place slowly, and the sudden reaction is avoided.

During the course of my observations I have suspected another cause for these sudden reactions. I have observed that they are not constant. Many patients do not experience them at any time during the treatment, some very slightly, and others to quite a marked degree. I have observed that those who have experienced them have done so both under a gradually increasing dose, and under a continuous uniform one. I have not yet observed them early in the treatment. When they are experienced, it is generally after the patient has been under the treatment for some time, or after rapidly increasing the dose.

These observations therefore have caused me to suspect an accumulative action of the serum. Case No. 10, has been the only one to experience them to a marked degree. And after each reaction patient has invariably felt good results.

Rules for administering the serum.—With a view of obviating the sudden development of the physiologic effect, I have taken the precaution that the point of the needle passes entirely through the skin into the elastic cellular tissues, and am also careful to force the serum very slowly into the tissues. If at any time an unusual pressure should be required to expel the serum we may be certain that the point of the needle is in dense and non-elastic tissue, which should be a guide for the exercise of caution.

The following are a few of the precautions which I have used in the administration of this serum. 1, I usually begin with the minimum dose of $\frac{1}{4}$ c.c.; 2, the dose is slowly but progressively increased until a reaction is produced; 3, when the reaction is well-marked no further injections are given until it has diminished and then a smaller dose is commenced and again slowly increased; 4, in very susceptible patients, when a marked reaction is produced by a small dose, the treatment should be given on alternate days until a tolerance is established, otherwise it is given daily; 5, in advanced cases or in those who react quickly to the treatment, it is desirable to proceed with caution; 6, with such cases I take the precaution of placing them in the recumbent position while giving the injection, and at the same time give them a moderately strong current of electricity.

Limit of tolerance.—The limit of tolerance varies in different patients. I have observed that those in the last stage of the disease with a high temperature tolerate large doses, and those well advanced in the disease with low temperature, usually respond to very small doses.

Ultimate effects of the serum. These may be summarized as follows: 1, it improves the appetite and sleep; increases the weight and strength, lowers the temperature, lessens the pulse rates, diminishes the cough and expectoration, stops night sweats and lessens the disposition to take cold; 2, it increases the production of young cells in the blood, diminishes cell disintegration, and increases the percentage of eosinophile cells.

Deductions.—From the effects obtained from the new serum, in the foregoing cases, covering all grades of the disease, I make the following deductions: 1, in

early incipency the disease can be cured and convalescence rapidly established; 2, in cases possessing strong family and personal histories pointing to a marked tuberculous disposition—the early use of the serum T. R., will bring about a rapid improvement, diminishing the susceptibility to the germs, and by this means prevent such cases from passing into the more active stage of the disease; 3, cases of advanced tuberculosis without mixed infections, show encouraging results; 4, cases in the last stage with mixed infections receive temporary benefit, the progress of the disease being partially held in check, but it is doubtful if a permanent cure can be established except, in rare cases; 5, a blood study is not only a reliable means of showing the condition of the patient, but also the progress of the treatment.

After making a careful study of the effects of the antiphthitic serum T. R., I am frank in stating that thus far it has given most gratifying results.

My results upon patients correspond very closely to those obtained by Dr. Carl Fisch, in his excellent laboratory experiments, reported in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Oct. 30; 1897.

The cases which I have had the opportunity to study demonstrate that if a diagnosis is made early in the development of the disease, this serum offers bright hopes of bringing about a recovery; and, furthermore, cases known to possess a strong tuberculous predisposition may, if the serum is made use of sufficiently early, increase the immunity, and prevent the disease from passing into the stage of active disintegration.

If the results continue to be as gratifying as those which I have already obtained, the antitoxic and bactericidal properties of the serum in tuberculosis in man can not be questioned.

Having received such excellent results from the antiphthitic serum T. R., on all cases commencing the treatment early. I believe they justify the conclusion that, if cases with a known tuberculous predisposition should take the treatment while they exist as such, it will check the disease from further development. If this point becomes fully established it will bring about a revolution in the treatment in tuberculosis: the treatment then being directed with as much energy toward preventing as toward curing the disease.

One other point should receive a passing notice. I have reference to the advantage of climate in connection with the antiphthitic serum T. R.

The climate alone, in nearly all of the foregoing cases, relieved the symptoms after the patients came to Colorado. The improvement, however, was marked but not complete, many arriving at a certain point then cease to improve.

The climate in such cases exhausts its power and they either remained apparently stationary or begin to lose ground.

Hence, I believe that the effects produced upon the majority of the foregoing cases show conclusively that the best means for bringing about continuous and permanent improvement in tuberculous cases, is to be found in the new antiphthitic serum T. R., aided by a properly selected climate.

205 Jackson Block.

Pilocarpin in Pneumonia.—Lidmanowski reports eleven cases of pneumonia arrested by the second or third day, passing at once into convalescence, by immediate treatment with large doses of pilocarpin, dose 0.1 gram a day. He ascribes its favorable action to the energetic leucocytosis produced.—*Wratsch*.

PERSONAL OBSERVATIONS IN PULMONARY PHTHISIS.

Read before the Clinical Society, Dec. 7, 1897.

BY THOMAS NEIL McLEAN, M.D.

Visiting Physician to the Elizabeth General Hospital and Dispensary, Member of the Clinical Society of the General Hospital and Dispensary, the American Medical Association, and the District Medical Society of the County of Union, N. J.

ELIZABETH, N. J.

After an experience of twenty-five years, I desire to present some conclusions, the result of my own personal observations in pulmonary phthisis. I use the term advisedly, on account of its comprehensiveness, including as it does all that has been known and taught from Laennec to Koch.

The preparatory or premonitory conditions which almost invariably exist in all cases of phthisis do not receive the attention they deserve.

Let us apply the principle of early recognition of these little departures from functional and organic integrity, to the disease in question.

They deserve to live, who by careful attention to the various functions of the body, keep the various mechanisms of their various organs in harmonious rhythm.

Ignorance does not pardon in the eye of the law, and the penalty must be paid even though it may cost the life.

Max Nordau says "the degenerate must die." An inheritance of conditions which must inevitably end in an early death, is the result of ignorance, crime and fatuitous circumstances, many, if not all, of which might have been avoided.

To educate the public out of this phenomenal darkness, and where they can not be educated, to legislate them out of it, is the duty of the medical profession. Out of the complex phenomena of a disease which presents such a diversity of symptoms and conditions, it has been my aim to determine what is the first appreciable departure from health, the most constant symptom, discernible by patient and physician alike, which would lead us to suspect that the individual in question is in danger of ultimately becoming tuberculous. Many of the disagreements between physicians as to the natural history of diseases have arisen from the fact that they have observed from different standpoints and from different starting points; the latter being of much greater importance than the former, for the standpoint may be changed from day to day but the starting point can only be changed as a confession that the *fons et origo* had not as yet been discovered.

A few years ago I arrived at the conclusion that the first symptom (aside from general malnutrition), is a slight cough or hack repeated two or three times on an average, on reclining, at night. This cough antedates the morning cough by a considerable period, varying in length in different subjects. It is a little thing, but its etiology is important beyond measure. It is the *diagnostic symptom*, which having been found and understood by the physician, gives him an enormous advantage in the prevention and cure of phthisis.

The patient believes himself to be in fair health. He has no pain, no cough at any other time, no disturbance of any other function, is only a little below par, and will sometimes deny that he has any cough, until told by the members of his family that they have repeatedly heard him cough, when he lies down

at night. This same evidence has been repeated to me so many times that I do not doubt its significance, and I consider it the test question "does he cough on reclining?" If there is a symptom prior to this, I have been unable to find it. The etiology of it, I believe to be this, viz: that the mere change of position from the erect to the recumbent, has produced an immediate change in the circulation of the blood and air in the pulmonary structure, disturbing the equilibrium which always exists in healthy chests, controlled by the natural tension through the vaso-motors. A temporary passive congestion or hyperemia is produced thereby, due to an insufficient expansion of the finer tubes and vesicles, the blood pressure being out of proportion to the air pressure, and the coats of the vessels being over-distended or varicosed by want of support, the blood currents come under the influence of an extraneous force, *gravity*, which never occurs in vessels whose coats are normal, except by complete inversion of the body or as in the hypostatic congestions of long illnesses.

The change to the recumbent posture immediately causes an increase in the distending force within the blood vessels, and a decrease in the amount of air in the tubes and cells. As a result of this, a backward flow of blood into the bronchial vessels, and a sensation of fulness or tickling is perceived in the region of the head of the sternum.

The cough that occurs is nature's own effort to remove this fulness, which it accomplishes at first with only a few long breaths and coughs. If this pathologic condition is not relieved early, it continues until it requires stronger and more prolonged effort in the act of coughing to remove it. The objective symptoms of this condition are found in a slightly diminished resonance of a higher pitch, slight depression under the clavicles follows this, and still later the mucous click or catarrh of the apex. Mensuration shows a deficient expansion above normal, often below, except in women, from the effects of corsets and other tight clothing, which they invariably insist is not tight, and can only be convinced by ocular demonstration with the tape line. (The tape line should never be out of the physician's pocket, except when he is using it.)

Auscultation reveals a still more important point; a diminished or absent true respiratory or vesicular murmur. This symptom, I consider of greater importance than all the other objective symptoms, and it is invariably found somewhat before and always associated with the gravitation cough.

In the wondrous mechanism of the lungs we find the ramifications of the pulmonary artery intertwining among the air cells, forming a close and delicate network of capillaries, in the interspaces, supported by the highly elastic structure of the air cells. Elasticity is one of the most distinguishing characteristics of these cells. They are in health never empty, and in death can only be emptied by force. With every inspiration, both air and blood are aspirated into the lungs. When air is in excess we have emphysema; when blood is in excess, we have congestion, which being continued indefinitely brings on in time an endless chain of pathogenic conditions which must end in death, if not relieved by proper systematic treatment. Of emphysema, I need only say that the emphysema which results from spasmodic bronchial asthma, is antagonistic to phthisis.

Now, I believe that all the influences which dimin-

ish nervous and muscular force, and their number is great, such as sedentary pursuits, the dark side of life, residence in low and malarial regions, clothing that prevents a perfect action of the diaphragm and chest walls, dissipation, indoor occupations, worry and many others, these all tend to shorten the respiration and diminish its depth; as a result of this a gradual dilatation of the capillaries takes place, in that part of the lungs where the vesicles are least distended a passive congestion is produced, and thus is furnished a soil that will nourish tubercles.

The force of the heart's action, often increased by excitement, by stimulants of any kind, by muscular effort, by normal tension of vessels altered by chilling the cutaneous surface, and other causes aid in producing a dilatation of the pulmonary capillaries, and thus the blood currents coursing through vessels which have lost their contractility come under the influence of this extraneous force, *gravity*.

It is to this immediate influence that we are to look for the explanation of this cough on reclining, which we may distinguish as the *gravitation cough*. This condition is so important that it seems deserving of a distinctive name in our nomenclature of disease symptoms.

Upon the correct explanation of this cough depends the entire treatment of phthisis whether bacillary or non-bacillary. It is as easily gotten rid of even when the conditions have gone so far as to produce cough in the morning with expectoration and pain in the subclavicular and interscapular regions from congested pleuræ. These last two stated conditions occur in the order in which they are mentioned, the cough in the morning with expectoration as a result of a longer continued gravitation blood pressure during sleep, producing exudation into the bronchi, which is expectorated on arising. This exudation may not come on until weeks or months have elapsed since the gravitation cough began.

The pain in the pleuræ comes on still later as a result of the damming up of the blood currents and vaso-motor paresis, producing congestion in that tissue.

I have associated these three symptoms or conditions, before speaking of treatment, because they are all removed by *mechanical expansion*. The function of respiration, unlike those of other vital organs, is placed under the control of the will, whereby the integrity of the pulmonary apparatus may be preserved, by maintaining a perfect function of these organs. This is indeed an important safeguard. It is impossible to maintain a perfect organ without a perfect function. This principle applies to all of the voluntary organs of the body, and more especially to the breathing apparatus, exposed as it is to the vicissitudes of climate, and dangers of infection by bacteria.

Jacobi has truly said that the "tubercle bacillus never attacks healthy tissue," and I believe it to be equally true, that when they have found a lodgement in the tissues of the lungs, we have as yet no drug that can be administered, by way of the stomach or through the blood by hypodermatic injections of sufficient strength to destroy them. We counteract the effect of their toxins and increase the resisting power of the tissues against their encroachments, and there our drug power ends.

I have used the term *mechanical expansion*, by which I mean a regular systematic *natural* method of increasing the capacity of the lungs, maintaining a

normal function and regaining it when lost. It is common among physicians to recommend mountain air to their phthical patients. The benefit of this procedure is beyond question, but of the great multitude of cases, there are comparatively few, who are able to profit by this advice. The science of climatology is one of great interest, inasmuch as at the present date it is capable of showing better results in the treatment of phthisis, than the more fashionable science of bacteriology or any other. We know that there are regions almost entirely exempt from phthisis, others where it is more commonly found, and others where it prevails in great abundance.

Solly, who is recognized as an authority in the science of climatology, says "consumption is most prevalent in proportion to the temperature and humidity of the climate: 1, in damp cold climates; 2, in damp hot climates; 3, in dry hot climates; 4, in dry cold climates; while in curative effects it is true in reverse order. This indicates in a general way, that dryness is a benefit, and humidity obnoxious to phthisis." He qualifies the statement by saying that "apparently, humidity apart from other factors, does not in itself produce phthisis." It is my opinion that our phthisis cases, here, do better in the winter even with our sudden changes of temperature and humidity, than in the warm, debilitating, moist air of midsummer.

In regard to barometric pressure, Solly says "that statistics show an almost steady rise in the percentage of improvement, from the ocean to the altitudes, and from this we learn, that as a rule, the consumptive improves the further he is removed from the sea, as shown in the contrast of percentage of improvement in a large series of cases; sea voyages 54 per cent.; low land climates, 57 per cent.; dry desert, 65 per cent.; altitudes, 77 per cent. Therefore, while the desert of Arizona will cure more cases of consumption than the sea air of the coast, yet it will not cure as large a proportion, as will the mountain air of the highlands."

Hirsch has shown, "that decreased barometric pressure tends to confer more or less immunity from phthisis. The marked decrease which is present in all high altitudes has been demonstrated by Egger, and others, to have a remarkable effect upon anemia, by increasing the amount and quality of the red blood corpuscles and hemoglobin; that the blood changes are brought about, not by the quantities of dryness, sunlight, or other climatic factors in high or other climates, but by the diminished barometric pressure, was proved conclusively by the classic experiment of Regnard, who, at sea level, kept a rabbit in a bell glass under diminished air pressure, equivalent to the atmosphere at 6,000 feet elevation for a month; when the rabbit was removed, it was found that the same blood changes had taken place, as occurred in rabbits transferred from sea level to a climate at 6,000 feet elevation." This experiment, instructive as it is, brings up another question, would the same changes in the blood have been produced in an animal breathing the same rarefied atmosphere of 6,000 feet with the density of atmosphere pressing upon the external surface of the body as exists at the sea level. That is, was the improvement due to the rarefied air alone which the animal breathed, or was it due to this combination with the diminished air pressure upon the surface, or was it due to the decreased pressure on the external surface alone?

There are those who claim the improvement in the blood is due to breathing rarefied air. I do not know of experiments having been made which prove this conclusively. Certain it is that the decreased barometric pressure upon the external surface compelled a greater expansion of the chest, opening up a larger surface for the interchange of the gases, and consequently a greater oxygenation of the blood, the greatest of all hematinics, with improvement in the digestive system as a result of increased oxygenation.

I believe it is the forced distention of the lungs and bronchi, to those who live at an altitude, that gives immunity against phthisis. Aside from the barrel-shaped chest of emphysema, the full round chest is an acknowledged evidence of healthy lungs. A flat contracted chest is a constant invitation to tubercle bacilli and an evidence of so called weak lungs. To imitate the effects of altitude has been my practice for over twenty years, and in the lack of suitable apparatus to assist them, to teach my phthisis cases the art of mechanical expansion. Among the various ingenious methods which have been devised I could find none that were free from objections, as they almost invariably increase the heart's action, which opposes rather than helps the purpose of their use.

I have practiced but two specific exercises, which nature herself teaches. The first is an imitation of the cough, and the second of a person stretching. In practicing the first we take in the air through a space between the lips, about a quarter inch in diameter. Some patients do not grasp the idea readily, or are not accustomed to whistling and require the use of a tube through which to inspire. When the lungs are filled to their utmost capacity the lips are closed and the cheeks bulged to prevent escape from the nose. The air is held until the excess of blood is driven from the lungs, as evidenced by a sensation of fullness in the forehead and slight reddening of the face. By holding the breath after a full expansion, the blood is squeezed out of the lungs into the general circulation, and by frequent practice of it the lost equilibrium is regained.

This action is equivalent to breathing at an altitude, or inhaling compressed air at sea level. The stretching exercise is performed in the same way with the addition of raising the arms, without flexion, directly above the head at the beginning of the inspiration, and lowering them upon the chest as soon as the lips are closed. The purpose of lifting the arms above the head is to lift the chest wall by means of the pectoral muscles. The effect of these exercises is seen in the immediate improvement of percussion note, with lowering of pitch, a rounding out of the depression under the clavicle; the voice changes from a throat to a chest tone, and the removal of the mucous click which has been diagnosed by some pathologists as a sure indication of tubercle. The true respiratory or vesicular murmur, the most significant sign of a normal chest, is restored in its entirety.

A continuation many times a day of these exercises results in a radical cure with no other medicine than that which is directed toward nutrition and the sustaining of the nervous system. All the symptoms heretofore described may return again as the result of neglect. The price of health is vigilance and effort. If the phthisical patient would live and be healthy he must work for it, and in the way I have indicated or by some similar method, or he will miserably perish, notwithstanding he may swallow all the drugs in the

dispensatory and be injected with all the serums and specifics, so-called, which are now obtainable. The expansion method of treatment is *nature's method*, and is helpful in every stage of the disease except when there is active hemoptysis from organic changes, at which time they should be stopped until the bleeding ceases, and then begun again with very slight force at first, gradually increasing to the utmost limit after a few days have elapsed.

When pleuritic adhesions have formed, whether bacillary or not, the expansion must be so graded as to avoid fresh exudation, or inflammation, being guided by the sensation of pain. The greatest obstacle to recovery by this method is the ossification of the costal cartilages in a contracted state of the chest; being permanent, it will squeeze the life out. Thus far I have spoken of treatment in the primary stage before organic changes have taken place to any very great extent.

I am often astonished to see what can be done by this method with phthisis cases after they have become tuberculous, with mucopurulent expectoration containing numerous bacilli, with afternoon fever, temperature rising to 101.6 and 102.4, pulse 120, night sweats, anorexia, emaciation and dilated heart. I have seen these cases clear up and remain for years perfectly well, when at the first examination it was impossible to make a diagnosis on account of the foul condition of both lungs, the tubes being filled with râles, the pleura sore, respiration only tidal and percussion dull. I defy any one to make an exact diagnosis in some of these cases in detail, as to the extent, kind and location of the diseased processes going on, until he has cleansed the tubes and opened as many of the alveoli as it is possible by expansion.

An easy diagnosis is made by the microscope, but to drop the diagnosis at that and treat the bacilli instead of the patient, is very unscientific, because we have nothing with which we can destroy the bacilli, and even if we could destroy them would it be wise to leave the chest in the same contracted condition, with choked tubes and capillaries, with exudation products in the alveolar walls and their cavities filled with epithelial elements ready for a new infection? More than twenty years ago, before we knew anything about tubercle bacilli, I treated phthisis patients by this method, who had cavities with all the accompanying evidences which we now know as bacillary phthisis. Some of them are living today, well and performing the duties of an active life. Some have married and borne children.

The following case illustrates the effect of expansion upon hemoptysis. This case I saw in his sixteenth hemorrhage. His disease was purely functional, a case of *lazy lungs*. I instructed him as to his breathing, and he has had no return in the last twelve years, being in robust health. As an illustration of the immediate effect of thorough expansion, without medicine which could affect the fever, upon a case which the microscope diagnosed bacillary. The patient had been under treatment about six months before I saw him; male, aged about 40 years; had considerable cough; had lost flesh and strength; some pain in right chest front and back, with diminished expansion.

Oct. 12, 1896, I found him with temperature 101.6, pulse 88; 13, same hour, temperature 100.6, pulse 88; 14, temperature 99.8, pulse 86; 15, temperature 99.4, pulse 88; 16, temperature 99.2, pulse 80; 17, tempera-

ture 98.6, pulse 80. After this the temperature did not rise above 99.4 until an attack of gripe on the 28th, when his temperature rose to 104.4; 29, 104.2; 30, 101.4; 31, 100.8. November 1, normal and so continued, never rising above 99.8 during November. His temperature was taken from three to five times a day. During the first half of December pulse and temperature both remained normal, when my attendance ceased. He continued to attend to his business (which was much in his favor as he was obliged to walk several miles daily) after his recovery from the gripe, and I have not seen him, as a patient, for nearly a year, during which time he has been about as a traveling salesman, enjoying good health. The immediate effect of this treatment is often so astonishing to the friends of patients, that in accordance with the prevailing sentiment among the laity, as to the incurability of consumption, they will refuse to accept the diagnosis, even of the microscope, and after a time become careless and forget the advice to keep the chest well expanded, until the same conditions recur, and the patient returns, again to be told the same thing and to go over the same plan of treatment, or changes his physician for some other kind of treatment. It is easier to take medicines, it is pleasanter to be told they have "only a little bronchitis" and need a little medicine to stop the cough and ease the pleuritic pain.

A quick confidence is gained in the physician who will thus treat them, but it is a deceptive confidence that lulls the patient to a fatal inactivity, and ere long he turns from one to another, until finally he has more need of the undertaker than the physician. These are the saddest cases we see. Their day of grace is passed; organic changes have taken place to such a degree that little can be done but palliate symptoms. There are many cases that progress rapidly toward recovery for a few weeks, and hope is high, when all at once they begin to complain of the labor of expansion on account of weakness of the diaphragm and chest muscles.

This is the point in their disease in which an immediate change to a high altitude becomes (in the absence of suitable apparatus to accomplish the same purpose) an absolute necessity to remove a portion of the incumbent atmospheric pressure upon the chest and abdomen, and thus lighten the labor of breathing, increasing the nutrition of all the tissues through a better oxygenation of the blood. This is the way by which the resisting power spoken of by others is, in great part, sustained, and may be aided by the administration of hematics; the hypophosphites according to the Churchill method, bathing, suitable food, out door life, still remaining under the watchful care of the physician. To those who can not avail themselves of this altitude treatment, this assertion that they are too tired to expand their lungs, is the beginning of the last stage, where there is no reasonable hope for recovery.

To this class of cases, however, the principles of "pneumatic differentiation" may be applied as an equivalent for altitude, and like effects produced in the patient's home at the sea level, as upon the mountains.

The pneumatic cabinet was designed for this purpose twelve years ago, and its action has been proved to be theoretically and practically correct, and is still held by some of the most distinguished men in our country, as second only to altitude, and as "the best

therapeutic device ever invented" for the home treatment of pulmonary phthisis.

An insurmountable obstacle to its adoption into general practice has been its great cost. Being a heavy steel cabinet, it can not be moved from place to place to suit the necessities of the patient, but being kept at the physician's office, it may be used for twenty to thirty minutes once or twice a day. Those days on which he needs it the most he is prevented from using it by the conditions of the weather. What we need is a portable apparatus of small cost which the patient can use at his own home under the direction of his physician, using it as often and as long as his case requires. Beneficial as these treatments by the cabinet have proved to be, in many cases bringing about absolute recovery from bacillary phthisis, its success is but a finger board, pointing to something better, yet to be produced, which shall enable the physician to give to his phthisical patients the equivalent of altitude, with the comforts of home and friends superadded thereto, coupled with his careful guidance, in everything that pertains to sustaining the vital forces, improving the quality of the blood by food, exercise, bathing, hygienic clothing and medicine.

Von Ziemssen, at the twelfth international congress at Moscow, last August, says: "Looking back over the history of tuberculosis we see a motley conglomeration of methods of treatment. All these have been discarded, and but two agents remain to be considered, tuberculin and climate.

"Koch's old tuberculin has been forgotten, the value of the new has not been proven, and most people doubt its efficacy.

"The complexity of the lesions makes a cure by means of a specific seemingly impossible. Fresh air has always been one of the requirements, but it is only of late that the advantages of high altitudes has been clearly demonstrated. Fresh air is not all; it is the altitude that brings about an excitation of the blood-making organs, and increases the corpuscular elements in the blood."

Senator "regards altitude second only in importance to fresh air."

Von Leyden says, "So far the only treatment that has given any positive success is the climatic."

The causative relationship of the bacilli to the disease is an important question. Tuberculosis is always produced by the bacilli, but all phthisis is not tubercular in all its stages. I hold that it is an incident in the course of the disease and not the primary cause of pulmonary phthisis. The tubercle bacilli may be found in the air passages of perfectly healthy individuals. It is not commonly found until after considerable organic change has taken place in the pulmonary structure. It can not then be rightly considered as the cause of phthisis."

Jaccoud enumerates a long list of pathogenic conditions and says, "These multiple and variable elements are the true causes of the disease, the microbe is only the instrumental agent."

Barton says, "Back of the bacillus are causes which are operating to produce malnutrition and a lowered vitality."

The evidence of an imperfect lung function as a causative agent is forcibly shown in the effect of the contraction of extensive scars upon the chest resulting from burns and scalds, thus favoring lodgement for the bacilli. Three cases of this sort were reported

last year by Dr. Hall of Denver, in which one side of the chest in each case was scalded during infancy, and pulmonary disease began on the contracted side.

The night sweats of phthisis need to be considered in this connection, because they are a direct result of insufficient pulmonary aeration and exhalation. The skin with its glands is complementary to the lungs and supplements their action by elimination of its exhalation, in double the quantity exhaled through the lungs, being a daily average of 30 ounces for the skin and 15 ounces for the lungs.

When for any reason the function of the lungs is impaired, so that the normal quantity of carbon dioxid is not exhaled, the skin supplements their action at a time when the auto-intoxication has become so great as to cause a temporary paralysis of the vasomotors, with relaxation of the superficial capillaries. The night sweats are always accompanied with increasing weakness of the entire system, and are generally considered the cause of the great prostration which follows them. I do not believe this. The sweat is the result of a specific poisoning, principally by carbonic oxid and the products of metabolism, and is a conservative process, while the exhaustion which follows is a result, not of the sweating, but of the poisoning. We have seen how quickly the skin responds to the demand put upon it in case of urgent dyspnea from any cause. If all this be true, it certainly is very unscientific to give medicines to check the night sweat, for by so doing the system is still further poisoned, the vitality reduced and the end hastened. I have not for many years used medicines to control this symptom, but have found that an increase of expansion systematically carried out uniformly relieves it.

An instance of this kind was recently seen in a case of phthisis in our own hospital. The action of expansion in relieving and stopping night sweats is the strongest argument I could ask for in substantiating the truth of my statement, that it is the poisoning that exhausts and not the sweating and we conclude that it is wiser to treat the cause than the effect.

For several years past almost the entire medical profession seems to have been captivated by the discovery of the tubercle bacillus, and have experimented with many methods and drugs with the hope of destroying them by medication. All these have failed. As well try to check the resistless current of a mighty river by catching the fish in its stream. There is probably not a single case of advanced phthisis in the country today under the care of a physician but what has been treated with creosote or guaiacol or their carbonates. Creosote and its allies, without affecting the vitality of the bacilli seems to have a beneficial effect, temporarily at least, upon the general conditions. This I believe to be done by its antiseptic power over germ life in the alimentary canal. The discovery of the bacillus, although an important addition to our knowledge of one of the stages of the disease, has resulted in no therapeutic advantage, but has rather diverted the attention of the profession from the clinical aspect and the various lessons to be learned therefrom, to that which is only one of the factors in the disease, one which without doubt may be in some cases primary, but which clinical experience proves to be only a resultant, and not the prime causative factor, in the great mass of pulmonary phthisis.

I believe there remains but one method worthy of

the undivided attention of the profession, viz.: Aero-therapy as indicated previously, and although it demands of the physician a greater outlay of time and effort for the benefit of his patient, yet I doubt not that ere long the principles of this science will be understood and practiced by the great majority of our hard working fraternity, because the results which follow are distinct and positive, and because there is nothing else which satisfies the requirements in every case, to such a degree as arotherapy, the science which is destined to take the highest place in all that pertains to the prevention and cure of pulmonary phthisis.

FIVE YEARS' SUCCESSFUL EXPERIENCE WITH A SPECIAL MODE OF TREATING PULMONARY TUBERCULOSIS.

BY CHARLES WILSON INGRAHAM, M.D.

BINGHAMTON, N. Y.

During the past five years I have given my exclusive attention to the special treatment of pulmonary tuberculosis, and during the latter half of this period I have developed a definite mode of treating this disease which has proved so successful that I shall endeavor to place the system before my readers in an accurate and thorough manner, believing as I do, that if this mode of treating these affections was generally and faithfully practiced, the mortality from tuberculosis could be sensibly reduced in a very short time.

The first thing is to make a careful examination, both physical and microscopic, to determine accurately that the disease is tuberculosis, and this examination should embrace a complete family history of the patient. The securing of an accurate and complete family history of consumptive invalids is too often neglected, and this neglect takes from the physician a powerful aid in treating his patient. It is important to know what diseases have existed in the family, and particularly if the patient has inherited a tendency to tuberculosis. Indeed, without the aid of a thorough family history it is impossible for the attending physician to advance an accurate prognosis. It does not matter how mildly the affection has attacked the individual, the prognosis advanced without first understanding the family history is worse than valueless. It is confusing. It may be the means of allowing the patient to follow a line of treatment far from correct, and totally incapable of successfully combating the disease. With a careful record of the physical condition, and the records of several successive microscopic examinations of expectorated matter, together with a thorough family history, the physician is prepared to commence treatment.

As concerns exercise, how much shall the patient be allowed to take each day? I determine this question with the aid of the fever thermometer alone, and my rule is this: If the daily average exceeds 100.5 degrees, I recommend that the patient take very little, or better still, no exercise; while if the temperature reaches or exceeds 101 degrees, I recommend the thorough application of the "rest treatment," until the temperature has fallen below a daily average of 100 degrees. The temperature must be below 100 degrees for the reason that once having ranged high, it must reach a low average, else it will quickly return to its former height when the rest treatment is discontinued and the usual exercise again begun.

The rest treatment is one important item, and but

for it many desperate cases which have made permanent recovery must have terminated fatally. This treatment is generally known and requires only a very brief reference. This treatment consists in the patient remaining in bed for several weeks, the time varying according to the condition of the patient, as closely as if suffering from serious acute disease, and the physician should forbid the patient from spending a part of the time lying on the couch or in an easy chair. To secure positive benefit the rules of remaining in bed continuously, arising only to have the bed aired, must be strictly adhered to. It is almost marvelous how rapidly a change for the better will occur with the adoption of the rest treatment, and generally so apparent is the improvement to the patient that he is willing to fulfill his part. There are many patients of this class whose recovery may hinge entirely upon the rest treatment, who will refuse to isolate themselves for a few weeks hoping that recovery will be effected without the necessity of following such stringent rules. Others believe they can not leave their business. Necessity compels others to follow some regular occupation.

I refuse outdoor exercise altogether if the height of the fever warrants, although I insist that the invalid remains out of doors all day in pleasant weather, advising him to sit quietly in some sheltered place. I never allow extensive general exercise when the slightest fatigue elevates the fever to a high point. In general also never allow the patient to become fatigued and never allow him to take his meals when fatigued, or after exercise. Always advise a half-hour rest before meals.

Chest expansion should be practiced; encourage the patient to practice expansion of the chest each day, that he may make a perceptible improvement from week to week. I have seen patients with a chest expansion of but two inches increase to six inches within two months. The permanency of recovery from pulmonary consumption depends much upon the chest capacity of the individual, and there is nothing which ensures disease resistance and vital power of the pulmonary organs better than a good chest capacity, while on the contrary experience shows that it is among those who have but little capacity that we find the consumptive invalids.

One of my favorite modes of encouraging chest exercise is to fill a ten-gallon bag with oxygen gas, which is the average daily amount I use in consumptive cases in whom it is indicated, and encourage them to reduce as rapidly as possible the number of inhalations required to empty the sack. Those who do not use the oxygen may be treated by filling the sack with pure air by the aid of an air pump. I have seen invalids who at first required sixty inhalations to empty the sack reduce the number of inhalations to twenty within six weeks, and cases showing this improvement have been by no means rare.

Having now disposed of the subjects of general exercise, rest treatment and chest exercise, I come to the subject of general therapeutics. The administration of drugs by the stomach in the treatment of pulmonary tuberculosis is attended with great uncertainty. No matter how plainly the drug may be indicated, and in a large percentage of cases more harm than good follows the use of drugs in this way. It is well known that the stomach is very weak in all cases of phthisis, from the very incipency throughout the course of the disease, and in a large percentage of instances the

digestive organs are totally unable to perform their ordinary functions of the digestion and assimilation of nourishment, and when there is added to this task the digestion and assimilation of medicines the result is disastrous; the patient receiving no benefit from the drugs, which the proper organs were incapable of assimilating, and at the same time the assimilation of nourishment is more or less interfered with. Hence if the stomach is scarcely able to perform its normal functions we can not expect to introduce into the general system through this medium, any form of medication with any degree of certainty, and in the treatment of tuberculosis where errors are very serious if not fatal, we must make use of means attended with the greatest certainty, and those means which are at all uncertain must not be adopted. It is better not to attempt any mode of treatment which will not, with a reasonable degree of certainty, accomplish benefit for the invalid. The first object to accomplish in the treatment of phthisis is to gain control of the tubercular processes in the pulmonary organs, and until this is accomplished the disease is not under control, or is progressing. We must prevent the extension of the tubercles already formed, check the activity of the bacilli in the tubercular processes, that the lung tissue already involved may be saved from total destruction. And finally we must prevent the multiplication of tubercles, and particularly the extension into lobes which have thus far escaped disease; for every lobe which can be kept free of tubercles, and in condition not only to perform its normal functions but to perform, as far as possible, the functions of the diseased areas, in addition to the work which falls to the lobe normally, is very necessary to recovery. Once in control of the tubercular formations, we are in position to treat the case successfully, but while they are progressive the patient is in grave danger.

The first things to do are the study of the temperature of the case and decide upon the plan to pursue as regards exercise, rest treatment, chest gymnastics, etc. I next decide upon the use of at least two nutritive preparations, and, thanks to our manufacturing chemists, we can find excellent ones made from nauseous, crude substances reduced to a state of palatableness and easy assimilation. I usually administer a petroleum emulsion and a preparation of cod-liver oil. The effects from the use of both are far superior to that from the use of either alone. By administering these preparations, and occasionally using vegetable bitters, acids and the like, to promote the appetite, administering digestive agents as required, to ensure complete digestion, and also ascertaining that the patient makes liberal use of beefsteak, eggs and milk. I am satisfied with the amount of nutrition which is reaching the system.

Aside from the use of occasional remedies to relieve symptoms as they may arise, I administer no remedies by stomach, other than those already named, but depend upon hypodermic medication for the administration of alteratives and altero-reconstructives.

In the early part of 1892 I depended upon the hypodermic use of gold and iodine to accomplish the necessary alternative and reconstructive action, but after a few months of unsatisfactory clinical use, coupled with the fact that both agents, particularly the iodine solution, were exceedingly painful, I discontinued their use, and took up a line of experiment, both clinical and chemical, which finally resulted in the following formula, as shown by actual chemical

analysis. The formula shows the amount of each agent in each fluid dram of the preparation when ready for administration, the chemical compound being dissolved in sterilized oil.

R Iodin	gr. $\frac{1}{2}$
Bromin	gr. $\frac{1}{14}$
Phosphorus	gr. $\frac{1}{100}$
Thymol	gr. $\frac{2}{3}$
Menthol	gr. $\frac{2}{3}$

The ingredients of the above formula are not prepared in common mixture, but are chemically compounded, with the result that the solution contains no free iodine or bromine, otherwise the pain following its use would be almost unbearable. The chemical solution is of a very bright cherry color, is distinctly transparent, and its hypodermic injection is attended with even less pain than attends the hypodermic injection of a solution of morphia. A common mixture of the ingredients of the formula produces a solution which is of a dark muddy color, is not transparent, and contains both free iodine and bromine. The above formula I perfected only after three years work, and though I was able to use the compound in the latter part of 1892, it was far from being an ideal chemical compound, and its use was both painful and very irritating locally. By careful study and continued experiment, I have succeeded in eliminating, one after another, the disagreeable and imperfect features of the solution, until during the past two years I have made but one change in the formula and that the addition of menthol. In 1895 I contributed an article to the *American Medico-Surgical Bulletin* descriptive of the use of this compound which was my first on the subject, and in this article gave my results from the treatment of fifty cases of pulmonary tuberculosis, which in brief showed nearly 90 per cent. of cures in twenty-one cases treated in the first stage of the disease, nearly 50 per cent. in fourteen cases treated in the second stage, while in the treatment of fifteen cases in the third stage none were cured, though several showed permanent improvement and are alive today. My success since the publication of the article mentioned has been in every respect equal, if not superior to the results here reported, and to this improvement I attribute the action of the menthol, which I thereafter added to the compound. There is one important feature of the action of the menthol in this compound, it is given off chiefly through the respiratory organs, and soon after taking the injection many can detect the odor of peppermint in the breath, which odor is more or less noticeable throughout the day. It has been shown recently that peppermint locally, by inhalation, is a valuable agent in the treatment of tuberculosis, and by this means the lungs are constantly bathed in atmosphere of menthol, with very decided benefit to the invalid.

By the use of this compound I have found it unnecessary to use any other medication, aside from that previously mentioned, and by relieving the stomach of the necessity of assimilating drugs, which can be hypodermically administered, an important point in favor of recovery is gained, and then also, by hypodermic medication, we are positive that a definite amount of remedial agents reach the system each day. The maximum daily dose of this compound, which on account of the contained chemicals I have named "bromine-iodine compound," is one dram. The fact that the patients report daily, with great regularity, for their treatments, and regularity is a factor notori-

ously abused by this class of invalids in taking medicines per stomach, has much to do with my successful results.

I use a special one dram hypodermic syringe fitted with oil-caliber needles, and usually give the injections in the back of the shoulder. So little local irritation occurs as a result of the injections, that many treatments may be given in a very small area, and I have yet to find the first invalid who can not stand the mode of treatment. The permanency of the recoveries which have occurred under this treatment is another special feature of the remedy. It seems to alter the general system to such an extent, and in such manner that the tissues and fluids of the body are fortified against re-infection. If proper care is taken of the syringe and needles, there is absolutely no danger of inflammation, induration or abscess as a result of the injections, with a properly prepared compound. The compound has proved of especial value in cases of tuberculosis with hemorrhages, and in a number of cases treated no hemorrhages occurred after the first week of treatment. I have every reason to believe that the proper use of bromine-iodine compound (and there is no reason why the general practitioner can not use the compound as successfully as a specialist), coupled with the system of general management and nutritive medication herewith outlined, will, if generally used, effect a decisive decrease in the fatality which attends the ordinary treatment of this disease.

80 Chestnut Street.

A REPORT OF THE TREATMENT OF PULMONARY TUBERCULOSIS BY THE INHALATION OF ANTISEPTIC VAPORS.

Read at the Meeting of the Mississippi Valley Medical Association in Louisville, Ky., October 8, 1897.

BY GEORGE W. JOHNSON, B.S., M.D.

Medical Superintendent of the Cook County Infirmary; Late Chief Male Physician to the Cook County Hospital for the Insane, Chicago; Fellow of the American Academy of Medicine, Chicago Medical Society, and American Medical Association.

CHICAGO, ILL.

The antiseptic value of drugs in the treatment of phthisis is well recognized by the profession. But how to administer them in sufficient strength and quantity to control the tubercular and septic processes has been the problem. If administered by the stomach in sufficient strength and quantity to properly saturate the lungs, the stomach and lower alimentary tract is so irritated that the digestive function is greatly deranged. Hence nature's method of controlling the disease by vital resistance is much impaired.

If introduced directly into the lungs by parenchymatous injection, so much irritation is produced that an exudate is thrown out which occludes the finer air passages preventing the introduction of the medicaments.

For two years I have had the medical direction of the Cook County, Illinois, institution. During this period I have treated a great many cases of pulmonary tuberculosis and have always given the patients the benefit of the latest researches of the profession. Each new hope has been inspired only to be soon blighted by some untoward effect. The class of tuber-

cular patients sent to the institution are far advanced in the disease and practically considered beyond human aid. They are simply abandoned by their friends and the physician to die. The inmates of the Cook County Infirmary number from 1,500 to 2,000, and of the Hospital for the Insane 1,400. Since about Feb. 1, 1897, all the tubercular patients have been isolated as much as possible. Since June 1, 1897, 260 patients have been persistently treated by the inhalation of antiseptic vapor, while general and constitutional treatment was followed. The diet for this class is a little better than for the other hospital ward patients. The vapor used consists of eucalyptol, oil of cloves, beechwood, creosote each 10 parts and liquid alboline 100 parts.

These medicaments are vaporized by compressed air of from fifteen to twenty-five pounds hydraulic pressure to the square inch. The vapor is respired from a mask fitting tightly over the nose and mouth and for a period of fifteen minutes each morning. While taking the vapor the patient is required to breathe as deeply as possible and as near the normal number of times per minute as he can. The vapor is not at all irritating and can be easily taken by the feeblest patients. From the 260 patients taking this treatment a clinical record of 40 cases has been kept, with reference to quantity and character of sputa and microscopic examination, temperature, pulse and respiration, cough, night sweats, physical examination and body weight. These cases were selected without any special reference to their condition. A study of the clinical record of these forty cases up to this time shows fairly good results. In every case the sputum is lessened in amount and a weekly examination shows a diminution in the number of the tubercle bacilli, great benefit is given in the relief of the dyspnea and is the first relief spoken of by the patient.

The respirations become deeper and longer, the temperature less high in the afternoon, in cases where a considerable number of treatments have been taken, the cough and night sweats are much relieved and sleep is undisturbed. Physical examination shows the lungs to be clearing up, the râles disappearing and the respiration approaching nearer to normal and in many cases, an increase in body weight.

An example of which is given in the following four cases:

Case 1.—F. S. Age 41 years. Laborer. Family history negative. Personal history: has been addicted to strong drink. Was admitted December 1896; was coughing almost constantly. Night sweats were profuse. Sputa in great abundance and teeming with tuberculi and pyogenic bacteria. He was much emaciated and very anemic. Had had several hemorrhages and the respirations were short and jerky. He was sent to the tubercular ward and treatment began, which at that time consisted of the administration of beechwood creosote and guaiacol by the stomach—pushed to as much as the patient could stand. He was given a tonic of iron, quinin and strychnin three times daily. A cough mixture of carbonate of ammonia was used. Patient was confined to his bed. The diet was as stimulating as could be provided. Gastro-enteritis developed and all medication was discontinued, except the cough mixture and the tonic. He continued to fail. When the compressed air apparatus was first put in the hospital it was thought best not to give him the vapor, on account of his feeble condition. On June 4 a thorough physical examination was made and the sputa examined for tubercle bacilli, which were found in abundance. His weight was 129 pounds.

Physical examination.—The following physical examination was made September 29 and corresponds with the former save in degree. Inspection: Color normal. No pigmentation. Emaciation but not so extreme. Retraction of left side of chest with impaired motion. Supra- and infra-clavicular retraction. Palpation: No friction fremitus. Vocal fremitus not marked on either side, slightly less on left side. Percussion:

Supra clavicular dulness bilaterally; slightly tympanitic note over anterior surface of chest on left side, due to lung retraction. General dulness over posterior aspect of chest. Axillary region, normal resonance. Auscultation: Respiratory murmur universally feeble, especially as heard over posterior aspect of chest. Expiration high pitched. Subcrepitant râles heard everywhere over anterior surface of chest. Vocal resonance increased bilaterally, more especially on left side. Pectoriloquy marked on left side over lower portion of lung. As ominous as this last finding may seem, this man has gradually improved and he now coughs very little, the night sweats are entirely absent, the respiration though still impaired is much improved. He has no hemorrhage. The quantity of sputa is small and the tubercle bacilli very few. In fact seven slides were examined before any were found. He feels much improved and has not spent a day in bed for two months. The p.m. temperature is two degrees less. He has taken 79 vapor treatments and weighs 133, a gain of but 4 pounds.

Case 2.—A. M. 56 years of age, Scotch blond, R. R. fireman. Family history good. Personal history: had syphilis twenty years ago. Has been coughing for two years. Was admitted May 18, 1897. At that time was so feeble that he was taken to the ward on a stretcher. Cough and dyspnea were so troublesome that he had to be bolstered up in bed nearly all the time. Had had hemorrhages and night sweats. Sputa were abundant and muco-purulent, and tubercle bacilli were found in great numbers. Weight 102 pounds.

Physical examination.—Inspection: Expansion very limited. Pigment over chest. Palpation: Vocal fremitus everywhere slight. Percussion: Dulness everywhere in greater or less degree except in axillary region. Slightly tympanitic in these regions. Dulness more marked in supra-clavicular regions anteriorly and posteriorly and over right middle lobe. Auscultation: Respiratory sounds very feeble almost completely absent over right middle lobe, vocal resonance being marked here, as well as lower posterior aspect of chest. Pleuritic friction well marked over apices, bilateral also on forced inspiration over lower extremities of lungs. Marked inspiratory dyspnea. This man has improved in all these conditions. His respirations are free. Has had no hemorrhage. Expectorates only in the morning on rising and then but very little. Four slides were examined on September 29, and bacilli were found. He has taken seventy eight vapor treatments and has gained twenty-one pounds since the first of June.

Case 3.—C. W. 44 years, German. Family history: Father died of pneumonia. Personal history good. Has been ailing for three years but has had no hemorrhage or night sweats. Cough was bad on admission in January 1897. At that time patient was feeble and anemic and expectorated great quantities of purulent matter, which was teeming with tubercle and pyogenic bacteria. Afternoon temperature ranged from 103 to 104 degrees. He weighed 105 pounds.

Physical examination.—Inspection: Color anemic. No pigmentation. Expansion limited, almost entirely absent on left side. Left side markedly smaller than right. Left shoulder drooping. Palpation: No friction fremitus. Vocal fremitus absent over anterior surface of chest on left side, also over left upper posterior aspect; normal over right side of chest. Percussion: Left supra clavicular region flat, infra clavicular region dull; gradually less dull down to third rib; right supra-clavicular region dull, below this resonant to sixth inter space. Posteriorly: dulness over supra-scapular region on both sides; dullness marked over entire left aspect; normal resonant tone in left axillary region. Auscultation: Tubular breathing over the left infra-clavicular regions with faint moist râles. Suppressed high pitched respirations over remainder of left side and posterior aspect of chest. Normal vesicular murmur over right posterior aspect. Vocal resonance increased over entire lung surface. This man's physical condition has improved wonderfully. His temperature never goes above 99 degrees, coughs but little and expectorates scarcely any. Has had no hemorrhages and sputum is almost entirely free from bacteria. He has taken eighty vapor treatments and gained ten pounds.

Case 4.—S. D. Age 40. English, clerk. Family history: Two brothers and two sisters died of tuberculosis. Personal history: Single, habits good. Was compelled to stop work and was admitted June 8, 1897. Was anemic and emaciated, cough very troublesome; nocturnal perspiration exhausting. Was failing rapidly. Sputa contained abundant tubercle bacilli. He began to take inhalations of the antiseptic vapor at once and has persistently continued. Weight 130 pounds. He is gaining steadily. Sputa and cough almost entirely absent. Dyspnea somewhat relieved. In all the following physical conditions he has improved.

Physical examination.—Has tuberculosis of the larynx. Color normal. Retraction of soft parts on inspiration more

marked in supra clavicular regions. Left side smaller than right side. Percussion: Supra-clavicular flatness bilateral. Dulness everywhere except small area in axillary region on both sides, where a tone of hyper-resonance is obtained. Dulness more marked on left than on right side. Cardiac dulness extends about one inch to left of mammillary line reaching only to left border of sternum. Auscultation: Subcrepitant râles over apices, bilateral. Mucous râles over left lower lobe. Bronchophony marked over apices, increased elsewhere. Broncho-vesicular respiration over upper lobes bilaterally. Examination of a scanty amount of sputa on September 29 showed but few tubercle bacilli. He has taken 100 vapor treatments and gained 10 pounds since June 8.

While there has been marked improvement in the symptoms in every case, some have improved very much more than others. These were a most unfavorable class of patients to treat, being in the advanced stage of the tubercular process with hemorrhages, emaciation, night sweats, anemia and, in fact, scarcely able to breathe at all. In the absence of a specific for tuberculosis, we believe that with proper apparatus and skilful and continued administration much is to be hoped for in this class of patients by the inhalation of antiseptic vapor.

The respiratory movements so limited in tubercular patients are increased; the catarrhal condition of the upper air passages and especially in laryngeal tuberculosis is removed, thereby aiding better introduction of air into the lungs. The pulmonary air-passages are rendered and kept in a more aseptic condition thus minimizing the danger of new invasion. The alimentary tract is undisturbed by strong and irritating drugs, giving ample opportunity for the increase of vital resistance, by suitable diet and constitutional treatment.

The treatment of this class of patients by the inhalation of antiseptic vapor is both rational and practicable. For when the vapor is properly prepared and administered it is so fine and non-irritating and so intimately mixed with air that it must find its way to every portion of the lung substance that air in any form reaches.

I am fully convinced, from my short experience, that if the proper apparatus is used and the vapor not too strong, and given for from fifteen to twenty minutes twice daily, together with bitter tonics and supportive diet, great relief if not ultimate recovery may be brought to this unfortunate class of sufferers. It has been proved that when the vapor is properly prepared and administered that it reaches the minutest ramifications of the pulmonary air passages in the healthy lung. This fact being established it is no longer the question; how can medicaments be made to reach the alveoli? But rather, how soon will the therapeutists provide us with a specific for the tubercle bacilli? This done the dread malady of tuberculosis will no longer be credited with one-fourth of our mortality. That so large a number of cases have been relieved of their most distressing symptoms together with physical improvement, inspires a new hope and ambition for more thorough and extensive investigation. Any method of treatment that brings relief to the class of patients that I have treated gives bright promise for those in the incipient stage of the disease.

Orthoform in Tuberculous Laryngitis.—Neumayer announces that orthoform will relieve the pain which renders swallowing difficult in tuberculous laryngitis, buccal ulcerations, cancer of the tongue, etc. The substance can be insufflated or the surface painted with a 10 per cent. solution of the hydrochlorate, renewing the application as often as necessary, orthoform being non-toxic. (*See JOURNAL*, Vol. 29, pages 700 and 1170.)

PULMONARY TUBERCULOSIS WITH SPECIAL REFERENCE TO DIET.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY HUBBARD WINSLOW MITCHELL, M.D.

Member New York Academy of Medicine, Medical Society of the County of New York, New York County Medical Association, Physicians' Mutual Aid Association, Ex-President Medico-Legal Society of New York, Ex-Visiting Surgeon Bellevue Hospital Out-Department.

The purpose of this paper is to set forth some practical observations acquired by direct clinical experience upon the treatment of pulmonary tuberculosis with special reference to the effect exerted upon it by a due application of certain dietary regulations.

THE NATURE OF PULMONARY TUBERCULOSIS.

Pulmonary tuberculosis is a true inflammatory process set up by a specific morbid influence in the delicate lung tissue and terminating in true ulceration and supuration of the lung substance. I will briefly recall the anatomy of the lung. The trachea divides into the right and left bronchi. These divide again into secondary and tertiary bronchi, and the subdivision continuing, the bronchial tubes grow more attenuated and more numerous as they subdivide. They also grow more delicate in structure, and when finally they reach a minute size, they are comprised only of a thin membrane lined with pavement epithelium resting upon an elastic fibrous layer. They are then known as the ultimate bronchial tubes. Each one of these terminate in a lozenge shape islet of delicate pulmonary tissue called a pulmonary lobule. Each lobule consists of a vascular membrane in the form of a sac, from the cavity of which are numerous secondary compartments divided by thin partitions projecting from its inner surface. These minute cavities are pulmonary vesicles. Their walls are distensible and elastic, and expand and contract during the respiratory act.

These minute pulmonary vesicles are surrounded by capillary blood vessels which penetrate their partition walls. The abundant elastic tissue in the walls of these pulmonary vesicles gives to the lung its property of resiliency. These pulmonary vesicles are also called air cells or alveoli, and are largest at the apex of the lung and smallest in the interior. The aggregated mass of the pulmonary vesicles form the spongy or parenchymatous tissue of the lung.

The lung tissue is nourished by the bronchial arteries, which ramify upon the walls of the smallest pulmonary vesicles. The blood is returned through the bronchial veins. The pulmonary vesicles are supplied with lymphatics and nerves, the latter being supplied chiefly by branches from the sympathetic and pneumogastric.

The nature of pulmonary tuberculosis is an inflammatory process called into activity in these delicate structures by the introduction of a special microbe, the tubercle bacillus, which can flourish and multiply only when brought in actual contact with these sensitive and extremely attenuated membranes.

ITS CAUSE.

When this microbe has succeeded in gaining a lodgment upon the delicate pavement epithelium of a pulmonary vesicle, its specific action at once springs into activity, and this is first a congestion of the capillary vessels of the part, which is speedily followed by a true inflammation.

Succeeding this is the formation of minute masses which are called tubercle. These tubercle masses are formed in great numbers upon the delicate walls of the vesicles, and in a short time undergo a process called caseation or softening. At the same time they break down the vesicle walls, so that several pulmonary vesicles are thus turned into one.

As this softening process goes on and the matter accumulates in quantity, it is forced into the smaller bronchi, thence passes during the respiratory act into the larger bronchi, and is finally coughed up and expectorated by the patient. The expectorated matters are yellowish or greenish in color, and under a suitable power of the microscope are seen to contain great numbers of pus-cells with bacilli more or less numerous, as well as broken down lung tissue.

It is doubtful if pulmonary tuberculosis is caused in any other way except that mentioned. Heredity plays a very unimportant, if any part at all. Not all persons who inhale bacilli contract this disease. It is only those in whom a special adaptability to harbor the microbe become its victim.

The microbe has a veritable struggle for life. Its journey from the outer world through the air passages to the delicate structure of the vesicle is not without danger to itself, and hence few of them only find a successful lodgment in the pulmonary vesicles, which they must do before they can begin their baleful work. Most of them are arrested and die before they can reach a point favorable for their development. Only the most vigorous life and the fittest are the survivors.

ITS CONTAGIOUS PRINCIPLE.

Pulmonary tuberculosis is contagious when the bacillus is introduced from some source where it has retained its activity and virulence, and when we remember that the sputum from phthisis patients contains great numbers of these bacilli, which are distributed widely through dust and the carelessness with which sputum is voided, it will be seen that the danger from contagion is great, and it is in this way that the bacillus enters the lung by inhalation and the disease is acquired, but contagion by contact with a phthisis patient, and by inhaling his breath is very slight indeed.

ITS SYMPTOMS.

When the bacillus has invaded the lung tissue the symptoms are quickly manifested. The patient develops a cough which seems first to be of a bronchial type and is marked with expectoration of a mucopurulent character. The early physical signs are those of bronchitis, but very soon dyspnea occurs and becomes more or less severe. Respiration rises from twenty to fifty per minute, and the general distress is usually well marked.

ITS HABITAT.

The tubercle bacillus can not exert its specific poisonous action unless it finds a congenial habitat, and this is what may be called an alkaline temperament, and this temperament plays a very important part in the acquirement and behavior of phthisis. Persons who are thin, tall and anemic, and those having red or sandy hair, or light blonde hair with a thin pallid skin, pale mucous membranes and weak sexual organs, are those who are very liable to tuberculosis, very much more so, in fact, than do the darker hued or more athletic persons, or those who have the acid temperament. In these alkaline subjects the disease seems to make

rapid progress, and it is in the apices of the lungs, where the pulmonary vesicles are of large size, that the disease seems to locate by preference. In the apex of one or both lungs cavities form more readily, and the disease seems more virulent than when in the middle or lower lobes, and it is these patients who are tall and pale and badly nourished, and whose blood is deficient in red globules who acquire phthisis very readily. The apices are almost always involved, and he resists treatment to a great degree. In these cases also, when the disease has made any progress, the poisonous principle of the disease, whatever it may be (ptomain, or absorbed poison from the tubercle), seems to pervade the entire body, and he has therefore diarrhea, night-sweats, hemorrhages, anorexia, thirst and mal-assimilation of the little food he takes. These patients offer a congenial habitat to the bacilli and fall before their ravages like the morning dew. They are so difficult to treat and so persistent that they seem almost malignant.

When such a weak lung or special temperament, or readiness to receive the disease is found, it becomes a ready prey to the immigrating microbe. In many cases where bacilli are introduced into the lung they are destroyed for some reason, and this reason is either an acid temperament, or an individual power to resist disease, or a failure to gain a favorable lodgment upon the thin and sensitive walls of the air cells.

ITS ECONOMIC VALUE.

It has been held that disease, and particularly tuberculosis, has a certain economic value in checking the over-population of the earth. In former geologic epochs the exuberance and over-production of animal life has been restrained and held in check by the operation of several influences. The lower orders of animal life that have been so prolific in development have been preyed upon by the higher species of animals who used them as food. Every order of animal life has found a destructive enemy in some other order, and this process of animals preying upon others has served in all geologic ages as a complete check upon the over-production of any one species.

With man, however, the case is different. There is no higher order of animal than himself to hold in check the rate of his increase. To control and repress his too great reproduction, other influences quickly sprang into action. They were three in number. 1, his own exterminating wars; 2, the fearful ravages of disease; 3, his individual vices.

Man's early tribal quarrels were very destructive and continued in activity until replaced by more fatal methods of modern warfare. These repressing influences acted with such mournful force as to seriously affect, on several occasions, the welfare of mankind. We see in the reign of the Roman Emperor Justinian, A. D. 527-565, that the influence of his wars, to which must be added the fauine and disease that followed, destroyed more than one hundred million of human lives and depopulated some of the fairest provinces of the earth. This destruction caused a visible diminution of the human race.

The ravages of disease have also acted as a potent check upon the increase of mankind. As he aggregated into communities and nations and lived in close contiguity with his fellows, he knew nothing of sanitary laws and hence suffered severely from sporadic and epidemic diseases. Plague and famine so baleful

in their effects were also the result of his ignorance. Tuberculosis played a malignant and destructive part, and it has been stated, destroyed one-third of all those who died of disease. Whether this special disease has any economic value or not we can hardly say, but the question is not without force when we observe closely the character and temperament of its many victims.

The individual vices of man truly have an economic value. Habitual criminals, the cruel and morbidly vicious, the drunkard with his insatiable desire for intoxicants, and the prostitute are all victims of disease, nervous and otherwise, and all lack the mental balance necessary to make them sound and responsible beings. It is from the ranks of these classes that the insane are so largely recruited, and fill our asylums with their mournful presence. When either of these classes are allowed unrestrained action to their vicious or intemperate habits, their career is brought sooner or later to an end, and the prison, the hospital or the grave removes them from the walks of the living world.

ITS OCCURRENCE IN THE LOWER ANIMALS.

In the animal kingdom certain species contract pulmonary tuberculosis more or less readily. The species that acquire this disease are those brought in contact with man, either in the feral or the domestic state. Among the feral group come first the great order of apes, which may be divided into two general classes, as follows: The cynomorpha or dog apes, and the anthropolomorpha or man-like apes.

These apes have been called the catarrhine apes, that is, having a nose with narrow nostrils and a thin septum.

Some years ago while visiting West Africa I spent some time on the Congo River and saw considerable numbers of baboons. They are very alert and mischievous, live in groups of twenty or more, and are fond of the dwellings of man, where their thievish ways cause them to be regarded by the natives as a great nuisance.

On several occasions while we were hunting, a group of baboons would be seen hovering over one of their number who appeared to be unable to move. It was easy to approach, as he was too feeble to escape. Inquiring of the natives I found that the baboons were frequently taken ill with some chest trouble which was similar to that from which the natives themselves suffered. This I learned afterward was phthisis, which is not uncommon among the blacks in the lower Congo districts.

The mandril (*cynocephalus mormon*) and the magot (*macacus sylvanus*) are also frequently met with on both banks of the Congo.

In the wild and almost uninhabited country about 150 miles north of Cape Town in South Africa the common baboon is very numerous, and is a most unwelcome visitor to the negroes, who suffer from their thievish and predatory ways. They have little or no fear of man.

An English officer told me the Hottentots and negroes often contracted phthisis on their periodical visits to Cape Town, and it seemed to me that the baboons contracted the disease from the sputum of these natives, which they carelessly voided in their gardens and about their houses. This gentleman had often seen sick baboons presenting the same symptoms as the natives when suffering from phthisis.

One day while hunting in the adjacent hills I saw a baboon lying upon the ground. On my approach

he made no attempt to escape, for he was extremely emaciated and had a severe and violent cough. At that time the existence of the tubercle bacillus was not known, but I felt sure that the baboon was suffering from what we now term pulmonary tuberculosis.

THE DOMESTIC GROUP.

The common ox (*bos taurus*) is so frequently affected with tuberculosis as to require the rigid surveillance of our great abattoirs by inspectors who are appointed for this special purpose. It is no doubt true that these animals contract the disease from their long and close association with man.

The dog (*canis familiaris*), and the cat (*felis domestica*) are both very liable to tuberculosis, and this would seem an almost self-evident fact from their intimate association with man.

The duck (*anas boscas*), the goose (*anser anser*), and the domestic fowl occasionally contract this disease. It is not improbable that other animals are victims to tuberculosis, but they have no especial interest for us here. We are especially interested in those animals whose flesh and milk we consume as necessary articles of our daily diet.

ITS DIAGNOSIS.

The diagnosis of pulmonary tuberculosis is usually very plain. The presence of cough, expectoration, emaciation, diarrhea, night sweats, loss of appetite, thirst, anorexia with hemorrhages more or less severe, are nearly always present and reveal the true nature of the disease. The unfailing test is, however, the presence of the bacilli in the sputum. Without bacilli the disease is not pulmonary tuberculosis *per se*. A very early diagnosis can thus be made. The competent and careful physician has little difficulty in arriving at a true diagnosis even without the immediate examination of the sputum. He may begin treatment at once, but must examine the sputum for bacilli in order to confirm his judgment. These examinations should be made frequently during treatment, that he may know if the bacilli are diminishing and whether his patient is really recovering.

ITS PROGNOSIS.

Pulmonary tuberculosis when not modified by treatment is an extremely fatal disease. No accurate percentage of deaths can be given, because these differ with many writers, but once the disease is allowed to run its course without treatment, and especially in one of an alkaline temperament and a generally anemic condition, it is a rapid and terribly fatal disease.

TREATMENT.

We are called upon to treat a very complex disease. At the very outset we must not forget that pulmonary tuberculosis is an inflammatory disease of the spongy tissue of the lung, due to a special microbe and followed by a true ulcerative and suppurative process in the delicate lung tissue. It may be described briefly as a special ulceration in the pulmonary vesicles with an expectoration of the suppurating matters, and any treatment which is destined to cure or even relieve it, must be addressed to this ulcerating condition of the lung.

To successfully treat a disease so lethal in character and so complex in nature, it would seem that some remedy which can be introduced into the body at short intervals and for a long period of time, something that will act as an antiseptic by saturating the blood and modifying or destroying the bacillus and at

the same time inflict no injury upon the organs of the patient, would appear to be an ideal remedy.

A considerable percentage of cases of phthisis belong to the alkaline temperament, and a remedy having an acid reaction would appear to be especially indicated. From experience, which has been considerable, I believe that a solution of the halogen group of salts, with the hypochlorite of sodium added in due proportion, is the best remedy to modify and perhaps cure pulmonary tuberculosis.

This remedy acidifies the blood when saturated with it, and almost immediately relieves the extreme cachexia, loss of appetite, weakness and night sweats which form such distressing symptoms. The cough which is nearly always present, sometimes distressing and even terrible, can easily be relieved by giving a mixture of iodid of potassium (10 grains) with a little sulphate of morphin ($\frac{1}{2}$ grain) and a syrup as a vehicle, or a capsule of quinin grs. iij. (.2) and pulvis opii gr. ss. (.03) may be given during the day and at bedtime.

For the hectic fever nothing is better than a capsule containing grams .26 quinin, and grams .0014 sulphate of strychnin once or twice daily.

Alcohol in the form of whisky or brandy is nearly always indicated, especially when the disease has made any progress, and when the vital powers are feeble and the pulse weak and rapid, I usually give 30 c.c. of whisky slightly diluted with plain or mineral water twice or thrice daily for perhaps a month at a time, and then omit it for a while according to the progress of the case. It can be resumed at any time subsequently. Wine and malt liquors should never be given, as they are apt to disagree with the stomach.

DIET.

Proper diet forms an essential part of the treatment of phthisis. When we are dealing with a severe and wasting disease the diet should receive especial attention. The physician must always prescribe such articles as are nutritious and easily assimilated. Meats of all kinds, fish, shell-fish and eggs may always be given. Rich soups of beef, mutton or chicken are especially valuable, and are palatable and nutritious. Puddings of the farinaceous kind with good bread and butter are also nutritious and well borne. Coffee with cream, strong tea, chocolate, milk and milk punch, may be given freely as beverages. Cooked fruits may be given cautiously, but never raw fruits, as they are apt to induce a troublesome diarrhea. High seasoning with salt, pepper, mustard and vinegar and other condiments are well borne and act as stimulants and assmilants to the digestive organs, and usually are agreeable to the patient.

I can not speak too strongly upon the inestimable value of cold water as a beverage in phthisis. We must remember that the blood is deprived of its watery parts to a large extent by the wasting action of the disease, and hence the thirst which is sometimes very great, and the hot and burning skin so often present. I always insist upon the patient drinking large quantities of cold water at any time without limit. He may drink ordinary potable water or use one of the many excellent mineral waters now so easily obtainable. Among those I like best are Vichy, Seltzer, Appollonaris, Poland Spring and the Great Bear Spring. All of these are most excellent waters, and when iced are palatable to the patient.

The daily warm bath is of great value in reducing the surface temperature. It can be taken any time

during the twenty-four hours. The temperature of the bath can safely vary from 90 to 100 Fahr., or even higher if agreeable to the patient

REST AND SLEEP.

Perhaps second in importance only to water, is rest and sleep. Phthisis is a wasting disease and the muscular power of the patient is largely lost through atrophy of muscular tissue, and any effort that is not absolutely needed is harmful. Let no restriction be placed upon his hours of rest and sleep.

In conclusion let it be remembered that a drug of an acid reaction is the one specially required, and that a wisely selected and generous diet, together with liberal potations of cold water, the bath and sleep, when prescribed by the wise physician, form the best means at our command to combat, relieve and cure the dreaded disease known as pulmonary tuberculosis.

747 Madison Ave.

ON THE DIET AND GENERAL CARE OF CONSUMPTIVES COMING TO SOUTHERN CALIFORNIA.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY GEORGE L. COLE, M.D.

LOS ANGELES, CAL.

When asked to contribute to this Section I recalled the fact that only a few days previously a patient consulted me who had recently been sent to this region by his physician in one of the Middle Eastern States. His doctor had told him to go to Southern California, find a place suitable to live in, receive the benefit of the climate and not waste his money on either physicians or drugs, to use his own judgment and when he thought best to return to the East. Not this case alone, but the many similar cases, impressed me with the fact that a few words along this line may result in benefit to some who may seek such a change in the future.

Imagine the responsibility thus laid upon the patient. How shall he find the place suitable for himself? How should he know where to find suitable lodgings and table? How shall he learn of the proper clothing to wear in a climate wholly different from that he has left? Most of all, how is he to judge competently of the improvement made at the end of three, six or twelve months, in order that he may know whether best to remain longer or return to his home? Because he finds himself transported from snow and ice to a scene in which sunshine and flowers abound, he immediately dons his summer clothing and succeeds in contracting a cold, if nothing worse. He takes his first day's outing in an orange grove and proceeds to demoralize his digestive apparatus by partaking of the golden fruit, unripe and unfit to eat. He returns to his temporary quarters at his hotel, to awaken the next morning in anything but an amiable mood in which to set out in search of a permanent location. His stomach upset, snuffling with a cold, he finds some pleasant rooms situated on the north side of a building. He does not notice the absence of the sun's rays from morning till night, but rather has his attention called to the "beautiful mountain view" by his would-be landlord, who is quietly reserving his sunny rooms for others more experienced in the requirements of the invalid. The patient does not notice that his room has no

device for proper artificial heat, or if he does notice the fact he is promptly informed that one of those abominations in which the country abounds, a kerosene heater, will answer all purposes. In such quarters he takes up his abode and succeeds in prolonging his cold until he has a genuine bronchitis and augmenting his diet with green fruit, serves to continue the disorder of his digestive organs, until, at the end of three or six months, he concludes that his own Eastern climate, with home comforts, is about as good for him as to live here with a constant dyspepsia and bronchitis. And really he has now arrived at the proper conclusion. He begins to wonder if his lungs are in any better condition than when he came to such an abominable climate. He seeks a physician, who has no data of his condition at the time he arrived in California, but who tries to put him right in matters pertaining to location, clothing, diet, suitably heated sunny apartments and other matters pertaining to his general welfare and comfort; possibly suggesting some remedies which may tend to relieve the bronchitis and dyspepsia which he has contracted. The patient stays a month longer and returns to his Eastern home in a worse condition than when he left.

What a different picture thus presented from that of the patient who, on first going to a new section in which there is such a contrast to that of his former home, seeks medical advice and is started out correctly at the beginning of his new experience. A careful physical examination is made and recorded, so that at some later time he may be intelligently informed as to the progress he has made, and some definite reason given why he should remain longer or return to his home. By knowing his history and physical condition the physician can direct him to a suitable location. And some location well suited to nearly every individual can be found within a radius of one hundred miles from Los Angeles. Any altitude from sea level to 6,000 feet can easily be secured, with comfortable quarters, and the patient may at the same time be guided to sections varying greatly in relative humidity.

Do not misunderstand me as pleading in behalf of our local physicians for remunerative fees. It is not this. But the manifest injustice done by many Eastern medical gentlemen to their clients in this respect when sent from home has caused so much needless suffering among this class that I can not forbear a word of criticism. At the same time I commend the host of Eastern physicians who provide their patients with suitable letters to physicians who, while not infallible, nevertheless do better in guiding the patient than he can do for himself.

TUBERCULOSIS AND VINEGAR.

Presented to the Section on Physiology and Dietetics, at the Forty eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN ASHBURTON CUTTER, B.Sc., M.D.

NEW YORK CITY.

The enormous amount of work done in bacteriologic lines as to tuberculin has been of such little avail as to treatment and prevention, that I have no hesitation in bringing before the Section in a few words, a record of work that has been done on other lines and to the glory of medicine in that this work has cured the desperately sick and prevented the pre-tubercular becoming tubercular.

Dr. John Christian read a Latin inaugural thesis at Jena, October, 1729, in which reference is made to the coagulation of living blood by vinegar which he says dissolves silica and poisons like viper's venom. He laid down the law, "*Causa coagulationis sanguinis est acidum.*"

In "The Relation of Alimentation and Disease," Dr. James H. Salisbury recounts his investigations made on 1,028 hogs fed with sour foods in 1858. Salisbury in the preface, page iii, says: "I had been a graduate of Albany Medical College, and in 1850 entered upon the practice of medicine. I was immediately and forcibly struck by the almost entire want of medical knowledge in regard to the true causes of disease, and by the consequent uncertainty that must and did exist as to the means of combating and curing pathologic states." Salisbury's first publication relating to foods that ferment into alcohol and vinegar and are thereby causative of consumption of the bowels and lungs was made in 1864 in the Surgeon-General's report of Ohio; this paper and the matter found in "The Relation of Alimentation and Disease" (published 1888) contain enough to show this investigator's work as to the relations of vinegar and tuberculosis; yet I believe that medicine was not wholly the chaos he considered it when he started to practice in 1850; honor to whom honor is due; honor to Salisbury for his colossal experiments in feeding hogs to death with sour foods. (I would that some of the quid nuncs in bacteriology would enlarge their ken and get away from the bacteria and study yeasts, alcoholic and vinegar.) Honor to the Europeans who recognized the souring properties of certain foods before the time of Salisbury's publications.

In the bibliography appended, much of which is from the publications of this ASSOCIATION, I show what has been done by an American writer:

BIOLOGICAL.

"The morphology of the blood in health is as follows:²⁸

"*Color*.—Bright, fresh, clear, ruddy, strong. Clotting, rapid and firm.

"*Red corpuscles*.—Arrange themselves in nummulations, or are scattered evenly over the field; normal in size; non-adhesive; central depression well marked on both sides; periphery well rounded, clean-cut. Hold coloring matter firmly. Pass readily to and fro through the fibrin filaments. Appear fresh and fair.

"*White corpuscles*.—Normal in size, not enlarged by internal collections of foreign bodies. Ameboid movements strong or not. Proportion, 1 to 300 of red corpuscles. Consistence good, not sticky. Color a clean white. Freely moving at will.

"*Serum*.—Clear and free at first sight from any form. After fifteen minutes, most delicate semi-transparent fibrin filaments appear, forming a very light network in the field, which offers no obstacle to the passage of the corpuscles."

The morphology of the blood in tuberculosis is as follows:²⁸

"*First or incubative stage*.—Red blood corpuscles are less in number, ropy and sticky more or less, but not much changed otherwise.

"*Second stage of transmission*:—1. Red corpuscles: Color pale, non-lustrous; not clear-cut, not ruddy. Consistence, sticky and adhesive. Coating of neurin removed. Not so numerous as in normal blood. Owing to the increased size and strength of the fibrin

and the stickiness, they form in ridges, rows, but not so marked as in rheumatic blood. They accumulate in aggregations of confused masses, like droves of frightened sheep. They adhere to each other, and are rotten, as it were, in texture. 2. White corpuscles: enlarged and distended by the mycoderma aceti, or spores of vinegar yeast, that are transmitted into the blood stream from the intestines. 3. Serum more or less filled with the spores of mycoderma aceti, or vinegar yeast. These occur either singly or in masses of spores, which is the common form in which they are found, wherever vinegar is produced. The fibrin filaments are larger, stronger, more massive, than in health, and form under the microscope a thick network which is larger, stronger and more marked in direct proportion to the severity of the disease or the amount of accumulation. Besides the serum is apt to be of a dirty ash color. The sticky white corpuscles, the massive fibrin filaments in skeins, and the yeast spores alone or combined, form aggregations, masses, collects, thrombi and emboli which block up the blood vessels of the lungs soonest, because exposed to cold air, the most of any viscus; the blood vessels contract and thus arrest the thrombi and form a heterologous deposit, which is called tubercle.

"The third stage of tubercular deposit.—These deposits increase so long as vitality subsists in the tubercle and surroundings. When vitality ceases, the tubercle softens or breaks down. Sometimes if the process is very slow and life slightly inheres in it, the proximate tissue undergoes fatty infiltration which preserves it from readily breaking down. The morphology of the blood is the same for the second and third stages of consumption.

"Fourth stage, interstitial death.—The red corpuscles are thinner, paler, much lessened in number, increased in adhesiveness, stickiness and poverty; devoid more or less of neurin. The white corpuscles are fewer in number, more enlarged, often ragged and rough. Distended with spores of mycoderma aceti; more adhesive, and sticky. *The serum.*—Fibrin filaments are thickened, stronger; more massive, and more skeins of them present. The collects of mycoderma aceti are very much larger and more numerous; in moribund cases, I have seen them so large as almost to fill the field of the microscope."

PRE-TUBERCULOSIS.¹⁹

"The idea that diseases have periods of incubation preceding their full development accords with other facts in animal and plant biology. It is to be expected that tuberculosis of the lungs, for example, has a pre-stage. In fact, pre-tuberculosis exists and clinically means that the morphology of consumptive blood is present to a lesser extent than in tuberculosis, that the essence of pre-tuberculosis is in these vegetations in the blood, which coming from the fermentations in the alimentary canal, pass the barriers of the intestinal epithelia and float about in the blood stream of consumption any time during one year before the necrosis or sphacelation or breaking down of the lungs, sufficient to be detected by the usual signs, furnished by auscultation and percussion. It is evident that in such spongy bodies as the lungs small deposits may escape physical macroscopic exploration. But the microscope will detect this stage."

VINEGAR AND HOG CHOLERA.^{19 38}

"Seven years ago, my son and I independently studied hog cholera, on a large stock farm in Western

Massachusetts, autopsying animals immediately after death: 1, by the disease, and 2, by slaughter in early and late stages of complaint, the proprietor giving us every opportunity of macroscopic and microscopic examinations of blood and tissues of his animals, as he considered his herd doomed. We found, independently: 1, the blood morphology of tubercle and embolism; 2, tuberculosis of lungs, bowels, skin; 3, recent fibrin clots in heart; 4, partial paralysis of hind extremities; 5, paralysis of nerve centers.

"Causation of this epidemic.—1. Steady feeding of ensilage which is loaded with vinegar and vinegar yeast; 2, swill food brought from outside; 3, cold weather; 1 and 2, predisposing causes; 3, exciting cause."

The hog physically is much like man: man is very much of a hog as to eating food that makes swill, and hence suffers much from tubercle.

WORLD WIDE RELATIONS.

The Esquimaux does not die of tuberculosis. He lives on animal food, yet for months of each year he breathes a vitiated atmosphere.

Tuberculosis ravages in the South where little good beef is eaten and instead very much of vegetable food. Some fifteen years ago a resident of Savannah, Ga., came under treatment in New York. He changed his mode of living and became a beef eater. Since that time all of his family have died of tuberculosis; he lives because of his beef-eating habits. The negro dies of tuberculosis. Causes, poor food, the mental strain of trying to reach the white man's level, and syphilis, with its grandchild scrofula, and tubercle.

Tuberculosis has ravaged in New England, especially the rural portion, with its diet of pie three times a day and baked beans, which latter, chemically, are splendid food for cattle, but for man not fit, unless cooked for many hours. Tuberculosis is now diminishing in New England because they are eating more beef and drinking more milk, although there has been very much of foolish opposition to the use of milk.

Cattle are dying in New England and other places of tuberculosis, and so long as the silo with its alcoholic and vinegary products is used, so long will farmers lose their cattle. A man imported a splendid herd from the Island of Jersey some fourteen years ago. He had a silo. He was expostulated with as to the dangers of feeding sour foods to his cattle. He persisted and all died of either tuberculosis or heart disease.³⁶

The easiest way to exterminate the Indian is to give him plenty of white flour and rum. Tuberculosis always follows.

There is no "royal road" to the cure of tuberculosis or its prevention. The various tuberculin treatments are based on the principle of injecting an attenuated dose of poison into the human system and—this poison, like strychnia and many other drugs, stimulates nature and in some lines by inflammation to cure the diseased lungs and joints. One that has been afflicted with cough, weakness, emaciation, pain and dread of impending death, would only too eagerly accept such a treatment, yet in its very best it only effects results, it does not touch causes, and when one sees men like Robert Koch wrestling on this line, while lives go out because they will persist in ignoring the causative relations of vinegar and vinegar yeast to tuberculosis, it makes one wonder at this neglect of general principles. So long as the cause is being put in the system,

so long will tuberculosis continue, and it is strange that these followers of Koch also ignore the positive relations of syphilis and scrofula to consumption. As far as I can learn the majority of medical men are using, as a basis of their treatment, animal food, but why should they gravitate to the other side and give the causes of the disease, to-wit, fermented milk foods, such as kumyss, etc., pastry, starches, sugars, vegetable foods of many kinds, that can not digest, because of the weakness of the bowels, salads that soon make swill, jellies and colloids, to name no more. These same men also neglect the value of the study of the morphologies of the blood, sputum, feces and urine, as laid down by American observers.

At whose door shall be laid the blame of the ignoring of the incalculable value of the diagnosis of the pre-tubercular state, which diagnosis can be made before the lungs are affected, and before there is any sputum to find bacilli in or diseased spots in the lungs for tuberculin to re-act on? This knowledge of the pre-tubercular state is of the greatest value to humanity of anything in the practice of medicine.

The Dr. Cyrus Edson treatment was based on so-called logical grounds as to certain relations of carbonic acid to the human body in tuberculosis, yet he adds pilocarpine to his remedy to stimulate white blood corpuscle activity. He therefore indirectly recognizes the presence of vinegar yeast in the blood and that anything which helps the action of white blood corpuscles will help the patient for a time. Why not put the ax to the root of the tree, and stop the formation of this vinegar yeast in the blood?

Some Europeans are now using raw beef. Why they do not give their patients broiled beef, I can not understand. Raw beef is unpalatable, it promotes tape worm. The use of beef is the bottom principle in the treatment of tuberculosis, but it should be employed in the form of steaks or roasts, or the first-class top of the round freed from connective tissues by machiue or knife and chopping bowl, as the connective tissues are of a colloid nature, and ferment, and tend to the production of vinegar yeast. The lean muscle pulp is then molded into a cake, an inch and a half deep, several inches wide, not too tightly pressed together, and in all of its preparation care should be taken to touch as little as possible the meat direct by the hands as the human animal heat will change the character of the muscle pulp; broil this over a bed of good live coals, a gas stove, or even kerosene flame, turning often, and the resultant should be of a dark brown color on the outside and of a reddish but not raw appearance inside. It is best served on a hot water plate and if a little under-done, it will cook on the plate when the meat cake is opened. If a hot water plate can not be obtained, one can be extemporized by the use of a soup plate filled with hot water on which is placed another plate with the meat. There can not be too much care used in the buying of the beef or its preparation and if proper caution is taken, the patient will generally eat it with a relish. It should be seasoned with pepper, salt, butter, Worcestershire sauce, horse-radish, lemon juice, as the patient desires.

Lamb, mutton, the dark meat of fowl and game; broiled cod-fish can be used, as changes; the whites of eggs dropped in boiling water and slightly cooked may be taken freely if the patient is not eating enough of solid food. Some patients will take the whites of from one dozen to two dozen eggs in a day when weak

and not able to take other food. Don't do as one woman did; she gave her husband the whites of eggs dropped in boiling water with plenty of vinegar. The masses of vinegar yeast in the blood were so large and frequent under the microscope that amazement was expressed. The woman protested that she was doing everything absolutely according to order for her husband. As all of his symptoms were worse and because of this blood morphology of the masses of vinegar yeast, it was insisted on that some error was being made and it was ascertained what she had done.

Vegetable food may be added as follows: Some patients can bear one of the following foods at a meal—cracked wheat, rice, hominy, toasted entire wheat flour bread, baked potato. It is a hardship at the best to confine patients to close diet and physicians should give them as much variety as possible, but there is more danger of error on the one side of too broad a diet than one of too narrow. The use of distilled water or some good spring water that has not more than five to ten grains of salt to the gallon should be persisted in, drank (after boiling) at a temperature of from 100 to 120 degrees Fahr. one hour before each meal and on going to bed.

Medicines should be employed in the treatment of tuberculosis on principles and the main one is give no medicine which can ferment into alcohol and vinegar in the alimentary tract. This principle forbids the prescribing of many cough syrups and other preparations now largely used.

The skin in tuberculosis is more or less loaded with the vegetations of vinegar yeast. There should be employed daily sponge baths. The water to be hot or cold according to the patient's desires. Ammonia and water in the proportion of two teaspoonfuls to a pint or the aromatic sulphuric acid one teaspoonful to a pint or even the nitro-muriatic acid, one-half teaspoonful to a pint, can be used with great advantage; rubbing with a saturated solution of spirits and salicin is a good means of tanning up the skin and the whole body.

Bacteria or bacilli are babies of vegetations which have become animalized by contact with the human body and human secretions. Robert Koch demonstrated their presence in the sputum of tubercular cases, for which he should receive due credit, but the work which antedates his in time and importance as showing the real cause of tuberculosis must not be ignored. The vinegar yeast found in the blood is the second stage of the bacteria, and is found there in the spore form and sometimes in tubercular cavities we get the third stage of development in the aerial filaments of the vinegar yeast.

Physicians could learn more as to relation of sour foods to tuberculosis in a few months time by experimenting on hogs (not guinea pigs or rabbits), by feeding a certain number with sour and a certain number with sweet foods, having all in the same building so that they breathe the same air. The beauty of this kind of work is that one can kill the animals any time one pleases and know just what is going on.

The agricultural experiment stations of the different States are fully equipped to make these investigations on hogs. It is necessary, however, that the microscopist who follows the experiments should have a fair working knowledge of the methods of the American observers who have been studying this subject for nearly thirty years on their patients and with animals. If it is right to rush abroad to Berlin to study cured

cases of tuberculosis, some of whom die the day after they are pronounced cured, there can be no harm in studying in America, all the work which made cured cases twenty-five years ago, for such cases are living now.

PROGNOSIS.

Granted a recognition of the relation of vinegar to tuberculosis, the prognosis can be more definitely made out, for if one is stopping a cause then one has some hope to base his belief of cure on. If one is simply treating results according to tuberculin methods and is still putting in the food which will undergo vinegary fermentation, the prognosis must necessarily be doubtful.

What is the experience of those who recognize the relation of vinegar and tuberculosis? Temperament here comes in. Some of the most appalling cases with many hemorrhages, with the evidence of cavities in both lungs unquestioned, as determined by physical examination of the chest and by the detection of the elastic and inelastic lung fibers in the sputum, have progressed most favorably under proper treatment. Others, who apparently had little disease, went down to death. The rule has had to be laid down that all cases except the moribund should have a chance for treatment. It is a most wonderful thing how nature endows these cases with hope. Some patients fight indomitably, and contrary to expectations they get well. It is not pleasant to look back and consider the amount of opposition which was placed in the path of those who twenty-five years ago were endeavoring to help these distressed patients.

But what will you do with cavities? The post-mortem evidences of many morgues and dissecting rooms show unquestionably that cavities do heal over and patients live to die of another complaint. My own wife showed three small cavities healed in the top of the left lung and two in the right. There was some fatty and calcareous degeneration going on in the base of the left lung; liver somewhat enlarged but normal in structure; no tuberculosis of stomach or bowels; heart normal in size and as to structure; yet all her symptoms for three years had been of heart exhaustion, needing the greatest of care and attention. Seven years before her death an eminent medical man stated that she had but three months to live; if her appetite for beef foods, and in fact for practically all other foods, had not failed three years before her death, she would probably have lived to old age. Of great courage, good judgment, she in her weakness for many months traveled close to the verge of the grave. Of strong affections, her love for her dear ones kept her alive a long time; yet something in her nervous system broke down as to appetite and her time eventually came.

It is cruel to take away from the very sick hope. There are many doctors of eminence and influence who literally are executioners because of their brutally taking away all hope. The passionate, anxious, eager holding on to life of the very sick is a matter of divine origin, and I do not propose to stand in the way of that divine gift of the desire for life.

Some patients die from money troubles. Others die from the long-continued opposition of their friends, relatives and medical men to treatment. It can be thankfully said that this opposition is dying out. Others die because they are associated in herds at the various resorts in the mountains of the South and West, and in sanatoria seeing and hearing the con-

sumptives all about them. Such suffer for the privileges of home. They have many comforts taken from them and are liable in going South, of getting into a blizzard and have to live in a shelter which is improperly made.

I wish to emphasize that the treatment of tuberculosis must depend upon the family physician. It should commence in infancy; the children should be properly fed and taught to avoid sweets and the vegetable foods which do not agree with them, and those who are so unfortunate as to break down with the disease must still be kept at home, or such change of air and climate made as can do good and no harm. There is no question that good air is a wonderful thing, yet we can buy oxygen and force the air alimination if necessary in our cities.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, FEBRUARY 5, 1898.

MEDICAL LEGISLATION.

We wish to call the attention of our readers in the first place to Professor WELCH's article in this issue, which in detail sets forth the reasons why the "Antivivisection bill" now pending in the Senate and known as the "Gallinger bill" (Senate 1063), should be strenuously opposed by every physician.

Professor WELCH says truly that medical and scientific men have never had adequate opportunity to present arguments against the bill before the committee. The aim of the bill is to abolish animal experimentation altogether, and that concession now to the antivivisectionists whereby this bill would be allowed to pass, would be a fatal mistake and so handicap physiologic and therapeutic experimentations that further advancement would be almost out of the question.

He denies the statements in the committee report that any considerable number of medical or *bona fide* scientific men have favored the bill, and very easily disproves the claims that animal experimentation has been of no value to medicine. He further says that scientific experiments upon animals have not been conducted with cruelty, and states that no single instance of cruelty on the part of a scientific experimenter has been proved or set forth. He says that in England physicians there at first yielded to the passage of a similar bill and are now confronted with the fact that it is practically impossible to conduct proper experiments in that country, and even such men as Lord LISTER are obliged to go to the Continent to perform ordinary experiments.

We must therefore continue to urge upon the members of the ASSOCIATION and readers of the JOURNAL

generally that they send personal protests to their Senator and Representatives, otherwise this most injurious and fanatical measure may pass the Senate.

In the matter of the Public Health Bill, the ASSOCIATION Bill has been introduced by Senator SPOONER of Wisconsin. It has been thought wise to change the title from "Department" to "Commission" of Public Health, which in effect means the same thing. We regret to say, however, that the bill which was introduced on the 27th of January, has (according to press reports) without conference or without consultation with anybody been reported unfavorably with unseemly haste by Senator VEST, who recommends instead a Marine-Hospital bill which was originally introduced by Senator CAFFERY, and to which we referred last week. It seems that Mr. VEST reported this bill favorably on the 19th of January last, but the favorable "report" consisted in striking out all the original CAFFERY bill after the enacting clause and giving the Marine-Hospital Bureau, under the Secretary of Treasury, authority to perform all sanitary matters throughout the United States, in case of epidemic riding rough-shod over every board of health or municipal authority which might possibly stand in the way. Both bills now go to the Senate calendar, the bill prepared by the AMERICAN MEDICAL ASSOCIATION and American Public Health Association with an unfavorable report, and that by the Marine-Hospital chief with a favorable report.

Every effort must be made to defeat this CAFFERY bill, Senate No. 2680, if the medical profession are not to be entirely overrun by this action of the Marine-Hospital bureau. If this arrogant scheme succeeds there is no longer any use for State or municipal boards of health. The Marine-Hospital Service will perform their duties for them, notwithstanding the fact that no medical man outside of this organization, or any medical society or set of medical men whatever, has asked for so sweeping a measure or one so contrary to all previous enactments in relation to the public health. The text of this despotic measure will be found in the public health column of this issue. If there be a State board of health in the Union or a municipal board of any consequence that does not fight it, we shall be very much mistaken.

Work hard and earnestly for the ASSOCIATION Bill as introduced by Senator SPOONER and may success crown our efforts!

THE ANOMALOUS, BRANCHING AND ACTINOMY-
COTIC FORMS OF THE BACILLUS OF
TUBERCULOSIS.

In the two first editions of "Les Bactéries," 1883 and 1886, by CORNIL and BABES, branching forms of the tubercle bacillus are described and figured. These bacilli were derived from old cultures.

In 1888 NOCARD and ROUX,¹ and METSCHNIKOFF,² each described in the cultures of avian tuberculosis

kept at high temperature the formation of capsules and curious rarefied and swollen forms. METSCHNIKOFF has also seen that the tubercle bacillus situated in the interior of giant cells can surround themselves with thick capsules, and BABES has described various forms of granules, metachromatic corpuscles, vacuoles, clubs and branching organisms, and their relation to the bacillus of tuberculosis.

FISCHEL³ and COPPEN JONES⁴ maintain that the bacillus of tuberculosis is not a bacterium but a fungus of a higher type, because it may present ramifying threads, clubs and metachromatic corpuscles. They are inclined to urge that it could be placed side by side with the actinomyces, because it may form a mycelium when it is deprived of air.

These ramifications are genuine branches. COPPEN JONES found, in the sputum, anomalous forms of tubercle bacillus that corresponded exactly in structure to the club-shaped masses characteristic of the actinomyces. In this connection it is interesting to recall that the lesions produced by the tubercle bacillus and by the actinomyces are closely related, both being classed as infectious granulomatous processes. Furthermore, that the patients affected with actinomycosis react more than others, except the tuberculous and lepers, to the action of KOCH's tuberculin, showing, it would seem, an analogous composition of the substances that produce the reaction in the patient's body.

BABES⁵ established that the club-shaped masses of actinomyces are formed by a secretion of the terminal extremities of the ramifying filaments. They constitute a sort of capsule and appear to play the rôle of protection for the organs of reproduction. BABES has also shown that the filaments of actinomyces are stained a bluish violet by GRAM's method, while the club-shaped masses are stained red by a solution of safranin and anilin oil, followed by the action of LUGOL's solution.

MARPMANN⁶ found, in a sputum very rich in normal bacilli, bacilli with club-shaped thickenings with distinct branchings, and also a few rather long threads. He observes that the tubercle bacillus belongs to those fungi which form true cellulose in the cell protoplasm and which give the reaction for cellulose. Such bacteria are, so far as known, all aerobic. Cellulose is not formed in anaerobic cultures.

FRIEDRICH⁷ succeeded in finding branching forms of the tubercle bacillus in the midst of the tissues, in cases of rapid experimental miliary tuberculosis. He produced such disease by injecting into the arterial circulation from the carotid artery of rabbits tubercle bacilli in physiologic salt solution. The animals died

in from twenty-four to eighty-six hours, and the miliary tubercles were then found in the majority of the organs. When the tissues were stained by the usual methods (EHRlich, ZIEHL, NEELSEN) the bacilli did not present any unusual appearances either in regard to form or arrangement. In the case of the animals which died during the first thirty days after the injection, the author succeeded in demonstrating the bacilli in the tissues arranged in a radiating form and provided with clubbed ends such as are characteristic of actinomyces. He succeeded in finding all these ends by means of staining with Victoria blue, differentiating with acid alcohol, and then staining with a solution of eosin and water. Because these peculiar forms appeared to be characteristic of the first stages of the disease, FRIEDRICH is inclined to believe that the view that the clubs observed on the actinomyces are degenerative forms, is erroneous.

BABES and LEVADITI⁸ injected into the meninges of the brain of rabbits pure cultures of tubercle bacilli of slight virulence. They found that two or three days later the bacilli had formed undulating threads and filamentous masses, surrounded by polynuclear leucocytes. At the beginning of eight or ten days the filamentous masses were found presenting radiating peripheral terminations. Such masses may have a diameter of from 20 to 80 micromillimeters. They are constantly surrounded by a zone of polynuclear leucocytes containing a few typical bacilli. About a month after the inoculation the filamentous masses were found to have acquired a diameter of from 40 to 80 micromillimeters and that they were very much like grains of actinomyces, the center being occupied by a substance which stained rose-red by EHRlich's method and in which were again recognized a network of threads of the thickness of the tubercle bacillus, and from this central network projected free ends, sometimes a little thickened, at other times assuming a distinct club shape. By GRAM's method the mycelium could be stained a violet blue, the club-shaped masses red by means of anilin oil, safranin and LUGOL's solution (like the actinomycetes). GRAM's method alone gave an isolated stain to the mycelium. The various pictures obtained are reproduced in the plates that accompany the article. The authors think it is not impossible that one may some day find that some of the apparent forms of human or animal actinomycosis are produced by the bacillus of tuberculosis, because they can not understand why such conditions may not at some time or other be produced, as they produced experimentally in their actinomyecotic form of tuberculosis. It should not be neglected to examine cases of actinomycosis by the methods which are usually applied to

the tubercle bacillus. When one takes into consideration the composition and the form of these peculiar growths of the tubercle bacillus it becomes necessary to bear in mind the advisability of placing this bacillus in the same group as the actinomycetes, that is to say, in a family intermediate between the bacteria and the *ascomycetes*. HAYO BRUNS⁹ proposes to call the bacillus of tuberculosis the myco-bacterium of tuberculosis, because of the occurrence of branching forms.

VITAL STATISTICS OF THE ELEVENTH CENSUS.

"Part I of the Report on Vital and Social Statistics in the United States at the Eleventh Census, 1890" has just been received from the Government Printing Office by the Superintendent of Documents, Department of the Interior. It is a large quarto volume of nearly 1100 pages handsomely illustrated with colored maps showing the distribution of mortality during the census year. The rates are presented and discussed by Dr. J. S. BILLINGS, Deputy Surgeon-General, U. S. Army, retired, as expert special agent on the subject of vital statistics. The data used in this voluminous report differ in completeness and accuracy according to the locality in which they were gathered. In a large part of the country the only record of deaths to be had was that obtained by the census enumerators as the result of inquiries in each family and this is considered to be deficient by from 20 to 50 per cent., but from the States of Massachusetts, Connecticut, New Hampshire, Vermont, Rhode Island, New York, New Jersey, Delaware and the District of Columbia and from a large number of cities outside of these States fairly complete records were obtained from the local health authorities. The death rate for the whole country was 13.94 per 1000 living, but for the States and cities having a good system of registration it was 20.38. In the latter the rate of the urban population was 23.48, of the rural population 15.66. In the non-registration areas the enumerators gave a death rate of 10.86 per 1000 as compared with 13.42 in 1880, whence it is concluded that either the healthfulness of the country has increased or that the enumerators' returns, as regards deaths, were less complete in the eleventh census than in 1880.

The death rate of males was generally higher than that of females, 21.54 as against 19.25 per thousand. The excess of male deaths occurred chiefly at the earlier ages. The death rate for white children under 5 years of age was 64.21; highest in the metropolitan district, 88.48; lowest in the rural districts of the registration States, 36.72. For colored children of the same age the rates were much higher, varying from 56.48 in the rural sections to 151.60 in the metropolitan district; and in all localities the male death rate was higher than the female. The deaths of children under one year of age gave an infantile mortality of

115.65 per 1000, still-births being included in the births and deaths. Were the still-births excluded the infantile mortality would be 97.60. In the registration areas this mortality was 182.25 or higher than in Great Britain and Ireland, Denmark, Sweden, France and Belgium, but lower than in the Netherlands, Italy, Switzerland, Prussia, Saxony and Bavaria.

The death rate of the colored population in the registration area was much higher than that of the whites, 32.40 as compared with 20.22 per 1000, the excess of mortality being most marked in the younger years.

For the married in the registration area the death rate for those 15 years and over, taken as a whole, was higher than for the single in the same age group, and was higher among males, 16.66, than among females, 13.42. If, however, the age group 15 to 45 years be taken, the death rate of the single males, 9.29, was higher than that of the married males, 8.95, while the death rate of the married females, 9.63, exceeded that of the married males and also that of the single women, 6.79. In the age group 45 to 65 years the death rate of the single males, 31.29 was much higher than that of the married men, 19.83, and the death rate of the single females, 22.0, exceeded that of the married women, 16.80. Many statistics in this connection show the relative death rates from various diseases, according to age and conjugal condition. Then follows a section on occupation in relation to death. The highest death rate occurred among the laboring and servant class in cities, 25.15; the lowest among the clerical and official class, 7.69. The rates for certain trades and occupations were higher than the average male rates for the same ages. The persons subject to these high rates were musicians and teachers of music, apothecaries and pharmacists, butchers, bakers, confectioners, barbers, bookbinders, plasterers and whitewashers. For all other occupations the rates were lower than the average. Among males in the professional class of occupations in the registration districts the death rate per 100,000 of their number from diseases of the nervous system, 250.70, was higher than the average rate, 158.96, from these diseases in all selected occupations. The rate for diseases of the respiratory system was also higher, but that for consumption was considerably lower. The death rate from suicide was higher in this than in other classes. There was no death among physicians and surgeons under 25 years of age in the registration States during the census year. The death rate of medical men from 25 to 45 years, 9.52 per 1000, was slightly above the average rate of the professional class at this age, 8.47, as was also the rate at 45 to 65 years (physicians and surgeons 21.15, professional class 19.11), but the death rate at 65 years and over, was much higher than the average of the professional class.

In fact, this census report contains a mass of information under the heading "Occupation in Relation to

⁹ Centralb. f. Bakteriologie, xvii.

Death," sufficient to provide trade journals with interesting paragraphs for many a week to come. The influence of season and locality are then discussed, but the greater part of the volume is given up to a study of the causes of death. This report will be valued highly by those interested in sanitary questions concerning deaths and death rates.

PHTHISIS AND INSANITY.

The close relations of tuberculosis to insanity have been matters of observation and comment since the days of ESQUIROL and GEORGET and the other early alienists of the modern period. The fact that the mental symptoms of phthisis were notably characteristic had also been still longer a matter of common observation and naturally assisted in calling attention to these relations and suggested a direct connection between the two. When more recent clinical studies had shown that tuberculosis was not only exceedingly common in the insane, but that a hereditary tendency to the one was often associated or alternated with that to the other disorder the relations of the two became still more striking and suggestive.

In former times, not so very remote, the mortality from tuberculosis among the insane exceeded that for almost any other complication; a distinguished French authority reckoned that at least one-third of the deaths were to be attributed to lung affections and usually to this one. Within very recent times, CLOUSTON, who is certainly a good authority on this subject, estimates that while the mortality from this cause has been greatly reduced, under the best conditions, the proportion of the insane in asylums who die from tubercular lung troubles is still three times as great as that of the average population outside. How much of this discrepancy is due to the general lowering of resistance to the disorder, to trophic debility from the as yet imperfectly understood brain abnormalities of the mental disorder and how much to the enforced sedentary life and to the congregation of the inmates, many of whom must be necessarily infected, is uncertain, but that both of these factors are in play is more than merely probable. Asylums or hospitals for the insane are almost inevitably overcrowded, at least that is true of the public ones; their inmates are notoriously neglectful of sanitary rules and even the utmost care by physicians and attendants can only partially compensate for these unavoidable drawbacks. Under such conditions it is only remarkable that in times past, before the infectious and contagious nature of phthisis was recognized, all our asylums were not perfect hotbeds of the disease, and that any other affections had a chance to figure to any extent in their mortality statistics. It is only within late years that special infirmary wards have been the rule or at least common in asylums; the consumptives are not yet commonly isolated; the prevention of the spread

of the infection is seriously embarrassed by the mental conditions and habits of the patients, and yet ordinary attention enlightened by a better knowledge of the nature of the disease, has probably reduced the mortality from this cause by one-third or one-half. That in the former times of our ignorance the tuberculous death rate was no greater than it was and that even remarkable recoveries took place and postmortems revealed in old chronic cases the cicatrices of cured tuberculosis, goes far to make one believe in a general comparative immunity or the non-malignancy of the infection. It has been proposed by some zealous sanitarian alienists to build isolation wards for consumptives apart from the ordinary wards or the infirmaries, and thus to stamp out or absolutely prevent the spread of the disease. Apart, however, from the reluctance of authorities to appropriate funds for what does not appear to them imperatively necessary, there is some question whether such provisions would be as effective as anticipated. Tuberculous disease is not as readily discoverable in the insane as in the sane; many of the characteristic symptoms are apt to be wanting, and the condition may be far advanced before recognition, even by a careful physician. Inasmuch as postmortems show that one person in every four or five has been affected with tuberculosis at some time or other, it seems probable that such isolation wards would only receive the well-marked cases, while less obvious cases would be constantly being received and circulating amongst the other patients. The possibility of infection may thus be still almost as great as ever, and probably even greater, from the false security preventing the watchful care on the part of those in immediate care of the patients not thus isolated. However desirable such accommodations may be, they are not an absolute security, and much can be done without them by the use of the ordinary sanitary precautions especially applicable to this disease.

Whether there is a special form of insanity caused by tuberculosis may be questioned by some, but it appears to be the experience of alienists that a certain type of suspicious melancholia is most frequently associated with this disorder. In paretics also, with whom the delusions are so generally of an expansive nature, they are apt to take on a melancholic type when associated with consumption. The exact relations of the insanity and the tuberculosis are not altogether clear; the mental disorder usually, according to CLOUSTON, antedates the other, but the latter can be often foretold by the character of the insanity. The prognosis of the mental disorder in these cases is not as good as when uncomplicated by phthisis, while the restoration of mental soundness is sometimes apparently facilitated by the lung disorder in cases of the expansive type of insanity. It would appear that this special depressive type of mental disease either par

ticularly favored the outbreak of phthisis or that it itself was often an early symptom of latent tuberculosis. Whichever of these views is accepted, the fact of their apparent relations is interesting and suggestive, and the designation of phthisical insanity appears to be warranted in the classifications.

The fact of the so frequent common heredity of phthisis and insanity, already referred to, affords another ground for suspicion of their close relations. CLOUSTON indeed believes that a combined heredity of the two is more perilous as regards the probability of either disease than the same of either one singly. That is, he holds that a person with one parent tuberculous and the other insane is more liable to both insanity and consumption than one who has both parents suffering from one of these two disorders.

As an evidence of the improvement that has taken place of late years in the asylum mortality from pulmonary tuberculosis, the statistics of seven American hospitals taken without special selection for a period of ten years, from 1888 to 1897 inclusive, gave a mortality of 22 per cent. Taking out one of these with the highest mortality from this cause the percentage was 17. Six American hospitals similarly taken, of which only the figures for 1897 were available, gave a percentage of 13.7, while withdrawing one of these with the exceptional percentage of 57.69, the mortality from phthisis of the remaining five was only 9.4 per cent. of the total deaths. It seems entirely beyond question that tuberculosis, even under the comparatively unfavorable conditions afforded by the insane in hospitals as at present managed and equipped, is to a large extent a controllable disease.

CORRESPONDENCE.

The Apothecary.

CHICAGO, Jan. 15, 1898.

To the Editor:—Several of my medical friends have called my attention to an article in your issue dated Dec. 15, 1897, under the heading "Is the Apothecary Shop Doomed?" Whoever wrote said article seemed to be under the impression that such is the case, but being an apothecary shop-keeper myself, I beg to differ with the gentleman. Facts will not bear him out and I hope to be able to explain that the apothecary is still alive and as long as there are physicians there will and must be pharmacists.

Twenty-five years ago, when I entered the pharmaceutical field, matters were widely differently from what they are today. The average druggist, as we called them then, had no education, merely a training. The boy started in some drug store by washing bottles, scrubbing the floor and other manual work. Gradually he worked his way behind the so-called prescription counter and within a few months' time he emerged a full-fledged pharmacist. Education at that time was not compulsory: there were no pharmacy laws, no board of pharmacy, etc.

Matters are widely different today. The law, as faulty as it is, has accomplished a good deal. The boy who enters the pharmaceutical field must show some qualifications or he can not register as an apprentice. When through his apprentice-

ship he must either attend a respectable college or take up his studies at home, as he must go before the board of pharmacy and pass an examination as registered or assistant registered pharmacist. He can not serve as clerk or manager or proprietor except he has given proof of a thorough knowledge of materia medica, chemistry, botany and all the branches connected with pharmacy. So you find him fully prepared to enter the pharmaceutical field; years of practical and theoretic learning have been spent, but what does he really find? Any number of physicians who are not able to write a prescription, machines who are merely acting as figureheads for the so-called "manufacturing pharmacist or chemist." They write for patent nostrums, articles they do not know themselves, they merely take the manufacturers' word for it. For instance, he specifies pil. rheumatic (Jones), not even knowing the different ingredients, merely knowing Mr. Jones, a large manufacturing chemist, as more able to prescribe than himself. If you ask the doctor why he prescribes such stuff he merely must acknowledge Mr. Jones' agent had talked him into it. This is the advanced age of medical profession and what the apothecary finds when he enters on his duties. Who lowers the pharmaceutical profession? Nobody but the physician. He uses Jones' tablets because they are handy and cheap and principally because the agent has assured the physician they will cure any ill from a headache down to a corn. If the physician would take the trouble and do a little more studying, get acquainted with the U. S. Pharmacopeia and Dispensatory he would not waste his time on such representative but prescribe what his brain will indicate and not Mr. Jones' agent. If such would be his case the public would be greatly benefited and the medical as well as pharmaceutical profession would rank a great deal higher. Your correspondent says, we merely act as agent for the wholesale druggists, but forgets the physician is merely a tool of the manufacturing chemist. We are compelled to load down our shelves with a dozen and more makes of pills, elixirs, tablets, fluid extracts, etc., merely to please the physician and his good ally, the manufacturing chemist. A certain doctor told me a few years ago if I used Squibb's fluid extract of ergot instead of the one he specified he would consider me a substitute, while every apprentice knows this is a standard preparation and can not be excelled. Against such stupidity even a pharmacist is powerless. You say a girl in a factory who does not know the difference between epsom salts and senna leaves is better fitted to make a pill or an elixir than a pharmacist, who has studied for years, who has spent time and money to be efficient in his profession. Is it necessary to answer such a silly question? A first-class pharmacist will not prescribe but will remain within his domain and merely fill prescriptions, but the physician retaliates by taking the bread and butter out of the druggist's mouth by dishing out samples to his patients which have been left at his office by the manufacturing chemist and which the poor patient must swallow merely to give the manufacturing chemist a chance to get rid of his well advertised compounds. Why not carry printed prescriptions to accommodate the manufacturing chemist, or still better, let the mule follow the doctor loaded down with the different packages of the manufacturing chemist; have them labeled by numbers to fit the sickness. Your correspondent ought to know by this time that toilet articles, perfumes, face powders, etc., are taken out of the hands of the retail druggist. The dry goods store, the department store, etc., have complete control of those lines and I hope they will keep it. A first-class pharmacist will not buy any tinctures, elixirs or ointments; he will take pride in making such preparations himself, except his friend, the doctor, compels him to purchase such goods by specifying a certain make. Compare the average druggist's tincture or infusion with the one you recommend and you will find the one is made from carefully selected herbs or roots, while the large manu-

facturer's make is rarely up to standard. The principal reason why the doctor should not dispense is a plain one. The pharmacist is a safeguard to the physician. No matter what mistake the doctor makes the efficient, educated pharmacist will correct it and many a life has been saved on that account.

The lot of the pharmacist is surely not a happy one. He is the servant of the people. He merely lives for them. He strains every nerve to accommodate the doctor as well as the general public, and what does he get for it? The physician allies himself with the manufacturing chemist to enrich him and to help himself, and the dear public wonders why men make such fools out of themselves.

But in spite of the manufacturing pharmacist, or better called manufacturing patent medicine maker, the apothecary shop-keeper will continue to exist and better days are in sight for him. Yours very respectfully, E. V. HERMANN.

"Poor Carrasquilla."

NEW YORK, January 31, 1897.

To the Editor:—"A discussion of serum treatment followed, in which poor Carrasquilla suffered. Excepting by his own countrymen, no results were reported from the use of his discovery, and the Germans, the English and others came down in full force to deny not only the usefulness but to argue dangers from its employment. . . . Poor Carrasquilla, to have traveled so far and yet found so little at the end of his journey."—*New Orleans Medical and Surgical Journal*, December, 1897, Special Correspondence on "The Berlin Leprosy Conference."

When the lion was sick, every beast whom he had wronged in his life came to have a blow at him; and when the ass had for some time contemplated this spectacle, with growing courage he actually went and tried a kick of his own. Such a thing happens frequently among men; but, whoever plays the donkey in such a case let him make quite sure that the lion is past revival.

Poor Carrasquilla! His serum treatment has been cold-shouldered in Berlin: he who had gone, his heart so full of hope, returns crestfallen; Dr. Dyer weeps over him, for when he read his paper on antivenomous treatment of leprosy, it was received with bated breath and was generally considered *startlingly bold*, and Dr. Dyer, thus encouraged (for he is, I suppose, responsible for the utterances of his co-editor) thought that his ideas would *revolutionize* the treatment of leprosy all over the world. This is interesting. Does not Dr. Dyer think that if anybody should have proposed to cure leprosy by roasting one side of a leper's body, such a proposition would also be listened to with bated breath? Such a treatment would probably be considered also as *startlingly bold*. Yet, would this checked breathing of a startled conference entitle Dr. Dyer to hope that the treatment of leprosy would be revolutionized by the views he exposed with such tremendous effect. How does he reconcile this hope, proclaimed with such a strange flourish of trumpets, with the conclusions arrived at by his adored conference ("long live the Berlin conference!")? *Has Dr. Dyer any logical fiber at all?*

It seems to me that if Dr. Carrasquilla is to be called poor, he who has at least some intelligible theory to stand upon, Dr. Dyer would deserve the name of a poor beggar, for his pretensions are based upon nothing at all.

ALBERT S. ASHMEAD, M.D.

Rubaiyat—a Persian Quatrain.

CHICAGO, Jan. 15, 1898.

To the Editor: In your review of the book, the "Rubāiyāt of Doc. Sifers," you fail to tell us what Rubāiyāt means. Will you kindly supply the defect? Yours very truly, S.

ANSWER—We quote the following from a work in the Public Library on Persian literature: "His poetry is wholly composed

of independent stanzas, called Rubāiyāt, consisting each of four lines of equal, though varied, prosody; sometimes all rhyming, but oftener the third line a blank. As usual with such Oriental verse, the Rubāiyāt follow one another according to alphabetic rhyme—a strange succession of grave and gay. . . . At all events each Rubā'iy is a separate poem and, however composed, finds its place in the manuscripts in accordance with its alphabetic arrangements and not its content. The late M. J. Darmesteter describes the Rubā'iy as a poem complete in itself, with its own unity of form and idea, and when wielded by a genuine poet unequalled in force by any other kind of Persian verse, the repetition of the rhymes enveloping and accentuating the silence of the third line, which is generally left blank, producing harmonies and contrasting sounds calculated to give a peculiar relief to the harmonies and contrasts of the idea."

Do Adult Squirrels Castrate Each Other?

CHICAGO, Jan. 25, 1897.

To the Editor:—I have read with much interest Dr. Edmund Andrews' article on "The Oriental Eunuchs," in the JOURNAL, Jan. 22, 1898, wherein speaking of the castration of animals and says anent squirrels: "Naturalists state that the black or gray male squirrels in fighting seek to castrate each other with their teeth, so that many of those taken by hunters are thus mutilated. As they do it only in adult life it does not materially change their general development." Commenting upon this, later, in a letter to the JOURNAL dated Jan. 25, 1898, he quotes the observations of Dr. A. S. Allen.

Being somewhat of squirrel-hunter myself I wish to confirm the report of Dr. Allen. I should say that fully one-half the male squirrels I have noticed were castrated. This is always done in early life, not merely in the nest as described by Dr. Allen, but also after they begin to run. It is always done by the male parent. The young are chased from limb to limb and tree to tree until exhausted, when the old ones deliberately remove the testes and scrotum clean from the body. The practice is not confined to the gray squirrel. I have noticed it more frequently among the large fox squirrels found in Illinois.

I believe such an operation to be impossible among adult animals engaged in battle. The operation is, in most cases, done so neatly with their sharp teeth that no vestige of tissue remains. At first I took it for granted that they were all females, although I could not account for their large size. The large size of these animals, the perfectly healed wounds and the seeming impossibility of performing such a neat operation in a fit of anger, as suggested by naturalists, would forbid the conclusion that such operations are ever performed in adult life. The castrated are much fatter than the perfect males.

The only cause which I could assign for this methodical operation is that of jealousy, which is shared by the farmer who lives in the vicinity.

The practice may be taken in its mental origin to the sexual mental state underlying the driving forth of young males by the old ones among social animals.

EUGENE S. TALBOT, M.D.

PUBLIC HEALTH.

The "Caffery Bill" as reported to the Senate January 19, by Senator Vest.—That "An Act granting additional quarantine powers and imposing additional duties upon the Marine-Hospital Service," approved February fifteenth, eighteen hundred and ninety-three, be amended by striking out the following words in section one: "And with such rules and regulations of State and municipal health authorities as may be made in pursuance of or consistent with this Act," and striking out section three and inserting the following in the place of said section:

"SEC. 3. That immediately after the passage of this Act the Secretary of the Treasury shall make such rules and regulations as are necessary to prevent the introduction into the United States of any infectious or contagious disease from any foreign port or place, or the spread of such diseases from one State or Territory, or the District of Columbia, into another State or Territory, or the District of Columbia, and such necessary rules and regulations as shall be observed by vessels or vehicles departing from foreign ports or places for ports or places in the United States to secure the best sanitary condition of such vessels or vehicles, their cargoes, passengers, and crews, which rules and regulations shall be published and communicated to and enforced by consular, quarantine, and customs officers of the United States and the State and local quarantine officers of the United States. All rules and regulations made by the Secretary of the Treasury shall operate uniformly, so far as climatic conditions will justify in the interest of the security against the introduction or spread of said infectious and contagious diseases, and shall not discriminate against any port or place. None of the penalties herein imposed shall attach to any vessel from a foreign port, or owner, or officer thereof, until a copy of this Act, with the rules and regulations made in pursuance thereof, has been posted up in the office of the consul or other consular officer of the United States for ten days in the port from which said vessel sailed, and the certificate of such consul or consular officer, over his official signature, shall be competent evidence of such posting in any court in the United States.

"At any port or place in the United States where the Secretary of the Treasury shall deem it necessary for the prevention of the introduction of contagious or infectious disease from a foreign port or place that incoming vessels, vehicles, or persons shall be inspected by a national quarantine officer, such officer shall be designated or appointed by the Secretary of the Treasury on recommendation of the Surgeon-General of the Marine-Hospital Service, and at any such port or place no vessel, vehicle, or person from any foreign port or place shall be admitted to entry or enter without the certificate of said officer that the United States quarantine regulations have been complied with.

"Any vessel sailing from any foreign port without a United States consular bill of health, and arriving within the limits of any collection district of the United States, and not entering or attempting to enter any port of the United States, shall be subject to such quarantine measures as shall be prescribed by regulations of the Secretary of the Treasury, and the cost of such measures shall be a lien on said vessel, to be recovered by proceedings in the proper district court of the United States and in the manner set forth above as regards vessels from foreign ports without bills of health and entering any port of the United States.

"National quarantine stations now in operation shall be conducted in accordance with the provisions of this Act, and the Supervising Surgeon General, with the approval of the Secretary of the Treasury, is authorized to designate and mark the boundaries of the quarantine grounds and quarantine anchorages for vessels which are reserved for use at each United States quarantine station; and any vessel, or officer of any vessel, or other person trespassing upon such grounds or anchorages, in disregard of the quarantine rules and regulations, shall be deemed guilty of a misdemeanor and subject to arrest, and, upon conviction thereof, be punished by a fine of not more than three hundred dollars, or imprisonment for not more than one year, or both, in the discretion of the court.

"And any master or owner of any vessel or any person violating any provision of this Act or any rule or regulation made in accordance with this Act, relating to inspection of vessels, or relating to the prevention of the introduction of contagious or infectious diseases, and any master, owner, or agent of any vessel making a false statement relative to the sanitary condition of said vessel or its contents, or as to the health of any passenger or person thereon, shall be deemed guilty of a misdemeanor and subject to arrest, and, upon conviction thereof, be punished by a fine of not more than five hundred dollars, or imprisonment for not more than one year, or both, in the discretion of the court.

"Medical officers of the United States, duly clothed with authority to act as quarantine officers at any port or place within the United States, and when performing such duties, are hereby authorized to take declarations and administer oaths in matters pertaining to the administration of the quarantine laws and regulations of the United States.

"The Secretary of the Treasury shall, whenever in his judgment it is necessary, make rules and regulations to prevent the introduction of infectious or contagious diseases into one State or Territory or the District of Columbia from another State,

Territory, or the District of Columbia, and when such rules and regulations have been duly made they shall be promulgated by the Secretary of the Treasury and enforced by the sanitary authorities of the States and municipalities when the State or municipal authorities will undertake to execute or enforce them; but if the State or municipal authorities shall fail or refuse to enforce said rules and regulations, or other rules or regulations made under the provisions of this Act, the President shall execute and enforce the same, and adopt such measures as in his judgment shall be necessary to prevent the introduction or spread of such diseases, and may detail or appoint officers for that purpose.

"Whenever yellow fever, cholera, plague, or typhus fever has passed the quarantines of the United States, or in any manner any one of these diseases has gained entrance or has appeared within the limits of any State, Territory, or the District of Columbia, the quarantine regulations of the United States, prepared under the direction of the Secretary of the Treasury, for the purpose of preventing the spread of such diseases from one State, Territory, or the District of Columbia into another State, Territory, or the District of Columbia, shall be supreme and have precedence of State or municipal laws, rules, or regulations, and the President is authorized to enforce the same and to control the movement of vessels, railway trains, vehicles, or persons so as to prevent these diseases from spreading from one State, Territory, or the District of Columbia, to another State, Territory or the District of Columbia, and to prevent unnecessary restrictions upon interstate commerce; and whenever, in accordance with the rules and regulations made as herein authorized to prohibit or permit the movement of vessels, railway trains, and vehicles, or transportation of persons, prohibitions or permits have been made or granted, any person violating said prohibition or permit shall be deemed guilty of a misdemeanor, and shall be subject to a fine of not more than one thousand dollars or imprisonment for not more than twelve months, or both, at the discretion of the court; and any violation of said prohibition or permit shall be reported to the United States district attorney for the district in which the offense has been committed, who shall thereupon institute necessary proceedings for the recovery of the penalty herein imposed."

That section six of said Act shall be amended to read as follows:

"That on the arrival of an infected vessel at any port not provided with the proper facilities for treatment of the same, the Secretary may remand said vessel, at its own expense, to the nearest national or other quarantine station where accommodations and appliances are provided for the necessary disinfection and treatment of the vessel, passengers, and cargo; and after treatment of any infected vessel, or inspection of any vessel not infected, at a national quarantine station, and after certificate shall have been given by the United States quarantine officer at said station that the vessel, cargo, and passengers are each and all free from infectious disease or danger of conveying the same, said vessel shall be permitted to enter and admitted to entry at any port of the United States named within the certificate. But at any ports where sufficient quarantine provision has been made by State or local authorities, the Secretary of the Treasury shall direct vessels bound for said ports to undergo quarantine at said State or local station."

That section eight of said Act shall be amended to read as follows:

"That whenever the proper authorities of a State shall surrender to the United States the use of the buildings, grounds, and disinfecting apparatus at a State or municipal quarantine station, the Secretary of the Treasury shall be authorized to purchase them at a reasonable compensation, or pay a reasonable rental for their use, if in his opinion they are necessary to the United States; and the expense of said purchase or rental is made payable from the epidemic fund.

"That the Surgeon-General of the Marine-Hospital Service shall, whenever he may deem it necessary, appoint in each port exposed to yellow fever, or where such disease has ever been introduced, a port sanitary inspector, who shall have been a practicing physician for at least five years before his appointment at said port, and who shall be familiar with the symptoms of the disease hereinbefore mentioned, and skilled in its prevention and treatment.

"It shall be the duty of the port sanitary inspectors or quarantine physicians so appointed to make careful examination of the sanitary condition and surroundings of the ports where they reside and for which they are appointed, and to report each month, or oftener, if required so to do, the facts as to the sanitary condition of such ports to the Surgeon-General of the Marine-Hospital Service, with such suggestions and recommendations as they may think necessary and proper. The said

port sanitary inspectors shall perform such other duties in treating yellow fever or other infectious diseases as the Surgeon-General of the Marine-Hospital Service shall direct; and they shall each be paid from the Treasury, upon vouchers signed by the Surgeon-General of the Marine Hospital Service, the sum of one thousand dollars annually, payable, in equal quarterly installments, on the first days of January, April, July, and November.

Osteopathy.—Decision rendered in the Appellate Court of Illinois, Third District, November term, 1896.

Eugene H. Eastman v. the People, etc., Wall, J., Appeal from Jersey County Court.

This is an appeal from a judgment for \$100 as a penalty for practicing medicine without license, under Par. 10, Ch. 91, R. S. It appears that the appellant was engaged in the practice of "the profession of osteopathy," as it is termed in the briefs; that he had an office where he received patients, and that he visited patients at their homes; that he advertised his system and his skill therein by publications in the newspapers and that he professed ability to understand and treat human ailments intelligently and successfully.

So far as shown his treatment consisted wholly of rubbing and manipulating the affected parts with his hands and fingers and by flexing and moving the limbs of the patient in various ways.

It is insisted on his behalf that because he used no medicines or instruments he is not amenable to the statute.

Par. 14 of Ch. 91 declares that "Any person shall be regarded as practicing medicine within the meaning of this Act who shall treat, operate on or prescribe for any physical ailment of another."

It is argued on behalf of appellant that this provision must receive reasonable interpretation, and that to "treat" implies the use of medicines or drugs of some sort, and to "operate on" implies the use of instruments of some sort. This is not so necessarily. Many of the minor operations are effected without the use of instruments by mere pressure, extension and flexing.

This of course implies some knowledge of anatomy and some skill. So, many forms of disease are treated by attention to the diet, habits and mode of life without resorting to medical remedies.

It is said by counsel that if the statute reaches this case it must include treatment by Turkish baths, massage and the like. We think not. The evidence shows that appellant held himself out as competent to treat and cure numerous diseases, such as all forms of fevers, cerebrospinal meningitis, catarrh, diphtheria, croup, pneumonia, asthma, indigestion, dysentery, kidney diseases, measles, paralysis and many others, including in fact a large proportion of the ailments common to mankind. He represented himself as a graduate of the new school of "Osteopathy" and held himself out as qualified to examine and treat all who might seek his aid. Herein he differs from those who give Turkish baths, massage and the like.

He professes to be able to diagnose and advise in respect to a long list of diseases and to furnish discriminating and efficient treatment to those who may come to him, and while he may rely wholly upon manipulation, flexing, rubbing, extension, etc., yet he professes to have skill and judgment in these methods, so as properly to adapt the treatment to each case, giving it what is appropriate in amount and with repetition at such times and to such extent as may be dictated by his knowledge and experience. By his skill in the use of his peculiar remedies or methods he claims to be competent to relieve and cure various ailments, and therefore he invites patronage. We are referred to the case, *Smith v. Lane*, 24 Hun. 632. The statute of New York is unlike ours, and the facts of that case are unlike these in the case at bar. We think the ruling there should not control here.

It is suggested rather than argued that as the title of the act in question is "An Act to regulate the practice of medicine in the State of Illinois," and as the constitution provides that no act shall embrace more than one subject which must be expressed in the title, any construction which would include a matter not within the practice of *medicine* must be avoided or the Act is unconstitutional.

"Medicine is the art of understanding diseases and curing or relieving them when possible."—Bigelow. "It is that branch of physics which relates to the healing of diseases."—Dunghlison.

This act is not restricted to any particular methods or remedies. Indeed these are almost innumerable, considering what are used and what have been discarded.

We are of opinion the proofs bring appellant within the act

and that he is liable to the penalty imposed thereby for practicing medicine without license.

It is urged the court erred in refusing to dismiss the suit for want of authority of plaintiff's attorney to institute the action.

It is shown by a recital of the clerk in the order of record that such a motion was made and overruled and that the defendant excepted.

This entry by the clerk in the orders of the court for the day is not sufficient to save the exception, and if it were there is nothing to show that the motion was supported by anything requiring the action of the court. Such a motion should be supported by affidavit or some matter of which the court should take notice, and must be preserved by a bill of exceptions. The judgment will be affirmed. *Affirmed.*

Filed June 16, 1897. W. C. Hippard, Clerk, Appellate Court, Third District.

Defendant paid fine and left the State.

The State Board of Health have won the fight.

Validity of Health Ordinance Prohibiting Sale of Fresh Pork.—The city council of Helena, Ark., passed the following ordinance: "Whereas, the municipal board of health of Helena, Ark., at a regular meeting, held on the 30th day of April, 1880, declared the sale of fresh pork detrimental to the health of the citizens of Helena; therefore, be it ordained by the mayor and council of the city of Helena: Section 1. That it shall not be lawful for any person or persons to sell, or offer to sell, within the city any fresh pork, or sausage made thereof, between the first day of June and October in each year," etc. Was this ordinance valid? The statutes of that State confer upon cities of the first class power "to prevent or regulate the carrying on of any trade, business or vocation of a tendency dangerous to morals, health or safety, or calculated to promote dishonesty or crime." Under this statute the city council of Helena undertook to prevent the sale of fresh pork "between the first day of June and October in each year." It obviously intended to prevent the eating of it in Helena during this time by prohibiting the sale of it. Again, the question: Was the ordinance passed for that purpose a reasonable or lawful exercise of the powers granted by the statute? The supreme court of Arkansas says, in its answer, Nov. 13, 1897, case of *City of Helena vs. Dwyer*, that fresh pork is an article of food of general consumption and, when sound and free from disease, is useful and nutritious. Like all other food, it may become unwholesome when eaten to excess. The quantity eaten, under ordinary circumstances, produces the sickness, when it proves unwholesome. Any food is calculated to produce that effect when eaten in the same manner. The mere sale of it is not detrimental to the public health. The fact that individuals may be made sick by it when imprudently eaten does not justify a city council in prohibiting the sale of it. For the same reason it could prohibit the sale of any or all other food. The most delicious food, that which is most liable to be eaten to excess, would be subject to interdiction. If it be conceded that the city council may prohibit the sale of any article of food, the wrongful use of which will or may injure the health of the consumer, then they can prescribe what the citizens of the city shall eat by prohibiting the sale of all other food. The legislature or any of its creatures has no such power. The exercise of such power would be a violation of the inalienable right of man to procure healthy and nutritious food, by which life may be preserved and enjoyed. It would be an interference with the liberty of the citizen which is not necessary for the protection of others or the public health; would be an invasion of his personal rights. For the reasons indicated, the supreme court holds that the ordinance in question was unreasonable, invalid and void.

BOOK NOTICES.

Elements of Latin. For Students of Medicine and Pharmacy. By GEORGE D. CROTHERS, A.M., M.D., Teacher of Latin and Greek in the St. Joseph (Mo.) High School; formerly Professor of Latin and Greek in the University of Omaha; and HIRAM H. BICE, A.M., Instructor in Latin and Greek in the Boys' High School of New York City. 54 x 7 1/2 inches. Pp. xii+242. Flexible cloth, \$1.25 net. The F. A. Davis Company, Publishers, 1914-16 Cherry Street, Philadelphia; 117 W. Forty second Street, New York City; 9 Lakeside Building, 218-220 S. Clark Street, Chicago, Ill.

This is an elementary Latin book for the use of students in

pharmacy and medicine and is well adapted for such use. It is well arranged and the exercises chosen are such as to familiarize the student with the work with which he is to engage. The only criticism we make is that the authors have seen fit to adopt the English system of pronunciation, which we think a mistake, inasmuch as no country except England has agreed to give the English vowel sounds to Latin words, and the student who undertakes to use the English pronunciation of medical terms in foreign countries, except England, will find himself not understood and his knowledge unavailable.

We regret extremely that a book in all other respects so worthy of commendation should have this defect. It is imperatively necessary that medical students, so long as they go abroad, should not be additionally burdened or handicapped by having learned the Latin terms (also used in foreign countries) with an insular pronunciation that can only be understood by the islanders themselves or their descendants.

Twelfth Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania. Two volumes, cloth, pp. 1194. 1897.

Volume I contains reports and minutes: reports of standing committees; annual reports of county inspectors and of cities and boroughs, and reports on quarantine, disinfection, epidemics and special sources of disease. Volume II has to do with conferences and conventions and includes many papers of interest read at these various meetings. This volume also contains circulars and forms concerning regulation of matters in the province of the State Board of Health, etc.

The Psychology of Suggestion. A research into the subconscious nature of men and society, by BORIS SIDIS, M.A., Ph.D., with an introduction by Professor William James of Harvard University. New York: D. Appleton & Co. 1898.

Much of the experimental part of the work although planned by Dr. Sidis was done in the Harvard Psychologic Laboratory.

The volume is divided into three parts. Part I, Suggestibility. Part 2, The self. Part 3, Society.

Those interested in elements and stages of self-consciousness, intercommunication between the two selves, will find very much of interest in this volume. Here we have the mental processes brought down by easy transitions into formation of geometric figures and algebraic equations.

"It is as easy as playing on this pipe." The work is however instructive to all interested in this latter day fad, whether they agree with the conclusions of Dr. Sidis or not.

Notes on Micro-organisms Pathogenic to Men. By the Surgeon Captain B. H. S. LEUMANN, I. M. S., London and Cambridge: Longmans, Green & Co., pp. 65. 1897.

This is one of the most instructive and interesting little works that has fallen under our observation. It contains more in fewer pages than any work on the subject in English. Each paragraph in his work has a marginal note index which for reference will be found very convenient.

It is based on lectures delivered at the Army Medical School at Netley during the winter session of 1893 and 1894.

Among recent small works on bacteriology this little one must take a prominent place.

The World's Almanac and Encyclopedia, 1898. Pp. 568, issued monthly by the Press Publishing Company. Pulitzer Building. New York.

This well known Almanac seems to have collected all the facts of the year and condensed them in a way to make them handy and useful. No almanac contains more information than this.

SOCIETY NEWS.

International Health Exposition.—An International Health Exposition is to be held in New York City, April 25 to May 31, 1898.

American Laryngological, Rhinological and Otological Society.—The Southern Section of the American Laryngological, Rhinological and Otological Society will meet in Atlanta, Ga., Monday March 28, at 10 A.M. in the parlors of the Aragon Hotel. An invitation is extended to the profession, and especially to members of the Society. Dr. A. W. Calhoun is Chairman and Dr. Dunbar Roy of Atlanta, is secretary.

Cumberland County (N. J.) Medical Society.—The January meeting of the Cumberland County Medical Society was held at "Hotel Stephens," Vineland, January 11, with Vice-President, Dr. Judson in the chair. Dr. Ware read an interesting paper on the "Old Time Doctor." A valuable paper on "Puerperal Eclampsia," was also read by Dr. L. F. Day.

The Denver and Arapahoe Medical Society.—At the annual meeting of the Denver and Arapahoe Medical Society held January 11, the following officers were elected for the ensuing year: President, E. P. Hershey; vice-president, H. B. Whitney; secretary, G. E. Tyler; financial secretary, J. M. Blaine; treasurer, E. J. Rothwell. There is great enthusiasm in the Society over the coming of the AMERICAN MEDICAL ASSOCIATION in June, and preparations are being made for the handsome entertainment of all delegates. Colorado will give them most hearty welcome.

NECROLOGY.

THEOPHILUS PARVIN, A.M., M.D., LL.D., ex-President of the AMERICAN MEDICAL ASSOCIATION, Professor of Obstetrics and Diseases of Women and Children, Jefferson Medical College, died January 29 after a short illness at his home in Philadelphia. About eight years ago, Dr. Parvin, when examining a patient, inoculated his index finger with specific poison and, recognizing the nature of the infection, he called the attention of the class to it on several occasions as a warning to them to be always on their guard. His health subsequently became impaired and he suffered with a severe form of chronic laryngitis which compelled him for a time to suspend his lectures; of recent years however, this affection had been overcome so that he not only resumed his course of lectures, but was able to accept complimentary invitations to address medical societies. He was also a prominent member of the Young Men's Christian Association, being especially interested in the evangelistic work among the colleges; he occasionally presided or delivered addresses on Sunday night religious meetings for students. About a month ago Dr. Parvin experienced attacks of difficulty of breathing and irregular heart action, and showed marked evidence of failing health, but it was not until the day before his death occurred that his attending physicians anticipated any serious result to his sickness. He leaves a widow and two sons.

Dr. Parvin was born in Buenos Ayres, Argentine Republic, Jan. 9, 1829, his father being at that time a missionary there. On the death of his father, when Dr. Parvin was only seven years of age, the son was sent to Philadelphia and prepared for college. He attended the freshman year in class of 1846, at Lafayette College, Easton, Pa., and then went to University of Indiana, where he was graduated in 1847. He then returned to Philadelphia and attended lectures at the Medical Department of the University of Pennsylvania, when he received his diploma in 1852. After spending two years as ship surgeon on a packet sailing between Philadelphia and Liverpool, Dr. Parvin went to Indianapolis, where he found a favorable location to practice his profession. In 1855 he accepted the chair of Materia Medica and Therapeutics in the Ohio Medical College at Cincinnati. Selecting the chosen field of labor in which he afterward became so distinguished as an author and teacher, he devoted especial attention to obstetrics and gynecology and entered the Faculty of the University of Louisville as Professor of Obstetrics, a position which he soon resigned in order to accept the same chair in the Indianapolis Medical College, which he helped to organize and establish. In 1872, Hanover College granted Prof. Parvin the

honorary title of Doctor of Laws. In 1883, Dr. Parvin was called to the chair of Obstetrics and Diseases of Women and Children in the Jefferson Medical College, a position which he most acceptably and successfully filled until his death.

The Obstetrical Society of Berlin made Dr. Parvin an honorary member and this distinguished compliment was also paid him by the Obstetrical and Gynecological Society of Edinburgh. He was a member of the International Medical Congress and attended the sessions at Washington, Berlin and Moscow. He was a Fellow of the College of Physicians and the Philosophical Society of Philadelphia, of the American Academy of Medicine and of the American Gynecological Society. He was elected one of the honorary presidents of the Obstetric Section of the Berlin International Medical Congress and of the International Congress of Gynecology and Obstetrics which met at Brussels. He was also a prominent member of a number of other medical societies both in this country and in Europe.

Dr. Parvin was a facile writer and lecturer, he had a pleasing frank expression of face and a clearness in expressing his thoughts which made him an attractive public speaker. Those members of the Association who were present at the meeting at Atlanta in 1879, when Dr. Parvin delivered his Address as President, will never forget the marked evidences of favor which were accorded him, and the enthusiasm that his words inspired in an audience not accustomed to demonstrations of the kind. Professor Parvin was a valued, though lately not a frequent contributor to medical journalism. He was a member of the Medical Editors Association and had served as its President. In 1886 he finished his work on the "Science and Art of Obstetrics," which has gone through a number of editions and is now used as a text book. He also translated Winckel's "Obstetrics" several years ago. He was one of the associate editors of "Sajous' Annual of the Universal Medical Sciences" and contributed important articles to several systematic treatises and encyclopedias of medicines and allied sciences.

The students of Jefferson College and the members of the Theophilus Parvin Medical Society passed resolutions of sympathy and condolence, and the Faculty of Jefferson College entered a minute recording their sense of loss to the community, to the College and to the world of science and letters by his death.

J. Q. A. STEWART, M.D., died January 25 at his home, Farmdale, near Frankfort, Ky., of Bright's disease. Dr. Stewart was born Feb. 13, 1829, near Louisville. At the age of 20 years he had secured a good common school education and had graduated in law. Before he had begun the practice of his profession the "gold fever" had broken out in California and he decided on the journey across the plains. Soon after their arrival in the mining camp he was chosen magistrate, and many were the interesting stories he has been able to tell his friends of his career as "Judge." After some years in California he returned to Kentucky. In 1859 he was graduated from the Kentucky School of Medicine and at once went to Daviess County to practice. As a practitioner he was successful from the start, and after a few years practice in the country he removed to Owensboro, where he lived, meeting with all the recognition, social and professional, offered by Owensboro, until his removal to Frankfort, in March, 1878, to accept the position of medical superintendent of the Kentucky Institution for the Training of Feeble minded Children, tendered him by Gov. John B. McCreary. It is rare in this day of practical politics that a governor in rewarding party friends, makes so fortunate a selection as was made in this instance by Governor McCreary. That his appointee measured up to the place in every way is evidenced by the prompt reappointment by Governors Blackburn, Knott and Buckner. He honored the position, and the sixteen years he passed in this institution were marked by a fidelity to duty, interest in his work, and an ability to carry it on never excelled in the history of our eleemosynary institutions. To show the esteem in which he was held by the parents of the children intrusted to his care, every one who could afford it removed their afflicted ones to Dr. Stewart's private infirmary, when his term as superintendent of the State Institution was ended. Whilst he would undoubtedly have met with a large measure of success in private practice, it is questionable if he could ever in a large city have done the amount of good that he now has to his

account. In the spring of 1893, his only son having graduated in medicine, Dr. Stewart bought the old Kentucky Military Institute, six miles from Frankfort, and established him in business as manager of the "Stewart Home." In the following year, upon the expiration of his term at the State Institution, Dr. Stewart resigned to be associated with his son in the management of their private infirmary. As an alienist Dr. Stewart is well known all over the continent and Europe. He has visited every public and private institution in the country, and did not, for many years, miss a single meeting of the superintendents. He was an ex-president of their association and contributed valuable papers at their different meetings. In the industrial reforms of feeble-minded institutions, he was the pioneer in inaugurating the teaching of useful trades to the brighter patients; gardening, carpentering, shoemaking, broom and mattress making to the boys, and sewing, washing, cooking and housework to the girls. The highest honor the profession of a State can show a fellow is an election to the presidency of the State Medical Society, and this was generously accorded Dr. Stewart at the Frankfort meeting in 1893.

BENJAMIN CHAMBERS LUDLOW, M.D., University of Pennsylvania, 1854, died at his home in Los Angeles, Cal., January 10. He was born in 1831 at Ludlow Station, Ohio, and when 30 years of age raised a company of cavalry whose services were offered to Lieut. General Scott at the opening of the civil war. The latter replied: "No cavalry will be required. The four regular regiments will be sufficient." Soon after he was made captain of Fremont's Hussars at St. Louis, Mo.; then an aide of Major General "Joe" Hooker at the battle of Chancellorsville, and served under Major General Meade as an inspector of artillery at Gettysburg, Williamstown, Wine Run, Rappahannock and in several minor battles. In October, 1864, Col. Ludlow was appointed Brigadier General, by brevet, for gallant conduct at Dutch Gap and at Spring Hill, Va., and was placed in command of the James and York river defences. He resigned from the army in 1865.

DEATHS IN THE PROFESSION ABROAD.—Jules Emile Péan, Paris, January 30. He was born at Chateau Dun (Eure-Et-Loire), Nov. 29, 1830, and practiced surgery continuously in Paris for more than forty-five years. He was easily at the head of modern French surgery, and in the whole surgical world it is doubtful if he had a superior as an all round surgeon. In 1865 he was appointed surgeon of the central bureau. Two years later he joined the staff of the Lourcine, where he remained five years, going then to Saint-Antoine, and finally to Saint-Louis, where he remained until 1892. He became famous for his success in the delicate operations of ovariectomy. In 1887 he was elected a member of the Academy of Medicine. Three years later he received the decoration of the Legion of Honor, and in 1893 he was made a commander. His many admirers in America will greatly regret to learn of his death, and will join the medical profession of his native country in mourning his loss, for Péan belonged not only to France, but to the world.—Dr. Stanislaus Danillo, lecturer on Mental Diseases in the St. Petersburg Medico-Military Academy, aged 49 years.—Dr. Carl Ritter von Rzehaczek, Emeritus Professor of Surgery in the University of Graz.—Dr. Tiburcio Padilla, founder and till his death editor of the *Samana Medica*, of Buenos Ayres; professor in the Colegio Nacional; physician to the Hospital de las Mercedes of that city; author of "*Guia Medical*" and a work on medical jurisprudence; co-editor of the "*Farmacopea Argentina*," etc.—Dr. T. H. Belval of Brussels, editor of the *Mouvement Hygiénique*, and founder of the Belgian Antialcohol League, aged 65 years.

W. ABRAM LOVE, M.D., Atlanta, Ga., died January 21, aged 74 years. Dr. Love was born in Camden, S. C., was graduated from the medical department of the University of Pennsylvania in 1846, and was elected superintendent of the Georgia Asylum for the Deaf and Dumb in 1850. In 1871 he was elected to the chair of physiology in Atlanta Medical College, and later president of the faculty, which office he held on his death. He was also a member of the State Medical Association and the AMERICAN MEDICAL ASSOCIATION.

CHARLES L. WELLS, M.D., Professor of Diseases of Children, University of Minnesota, Minneapolis, died January 20, from pneumonia. Dr. Wells was born in Pompeii, N. Y., 56 years ago; was graduated from Geneva Medical College in 1869, and ex-president of the Minnesota Academy of Medicine.

SMITH BUTTERMORE, M.D., Connellsville, Pa., Dec. 28, 1897, aged 68 years.—Joseph R. Chaffers, M. D., Worcester, Mass., January 19, aged 40 years.—John C. Corley, M.D., Bloomington, Ill., January 27.—Charles Gangloff, M.D., Pittsburg, Pa., January 22, aged 51 years.—W. L. Hallam, M.D., Bloomington, Ill., January 24, aged 45 years.—Frank A. Mitchell, M.D., Bridgton, Maine, January 23.—R. C. Rice, M.D., Smithland, Iowa, January 25, aged 60 years.—Chas. Slaughter, M.D., Duluth, Minn., January 23.—Shep. A. Rogers, MD., Memphis, Tenn.

MISCELLANY.

Coxitis Tuberculosis.—F. König considers a radiograph an indispensable preliminary to operation, although simple granulating foci cast no specific shadow. But degenerated bones, especially caseous infiltrations, are shown well in the photograph, except in the case of very young children.—*Klin. Therap. Woch.*, January 1.

Tuberculosis of the Tubes.—Jacobs recently operated on a young woman to remove an enormous abscess of the left tube, which proved to be tuberculous, and later the right tube had to be removed for the same cause. There are no other manifestations of tuberculosis, and the patient seems now in the best of health.—*Presse Méd.*, January 1.

Tubercula R.—The latest reports published continue to be unfavorable to Koch's new tuberculin: the disease seems to continue its course unaffected by the injections (Stempel, 23 cases; Spiegel, 21 cases, *Münch. Med. Woch.*, Nos. 48 and 50, 1897). The greatest benefit has been derived from it in lupus, and here and there are a few who endorse it enthusiastically. In closing the series of articles the *Deutsche Med. Woch.* has been publishing on the subject, it remarks that several years must pass before the value of the Koch treatment is finally established.

Differentiation of Tuberculosis of the Salivary Glands.—Frequently produced experimentally, this localization of tuberculosis in man is extremely rare. O'Zoux describes two cases, distinguished from simple adenitis by the large size of the tumor and its location close beneath the edge of the lower maxillary bone. It is very painful and less solid around the edges than an adenitis. The pus is thin and not very abundant. The sound everywhere meets the same resistant, squeaking tissue.—*Archives Clin. de Bordeaux*, 1897, No. 1.

Pancreatic Diabetes of Tubercular Origin. Carnot states that specific tubercular lesions are very rarely found in the pancreas, which reacts to tuberculous infection with sclerosis, caused evidently by the products of the bacillus, as the bacillus itself disappears very rapidly. Experimentation with dogs produced a similar sclerosis reaction, with or without glycosuria, according to the progress of the sclerosis in most cases. When there was no trace of glycosuria, the necropsy usually showed part of the organ still intact or regenerated. When the sclerosis in man becomes total diabetes follows. *Gaz. d. Osp. e d. Clin.*, January 4.

Lupus and Tuberculous Ulcerations of the Ano-rectal Region.—A recent thesis by Dimitroff observes that this affection is not so rare as supposed; one has only to look for it. The infection is sometimes from without: accidental contact with infected clothing, etc.; sometimes from tuberculous sputa, possibly of auto-origin. The development of the bacilli is favored by hemorrhoids, constipation or diarrhea, traumatism, etc. He

adds another to the seven observations on record. A comparatively healthy young man, affected for two years with tuberculous erythematous patches and ulcerations, which were excised and the loss of substance substituted by a flap from the surrounding region. The result was excellent, and excision is recommended whenever the lesions are too deep to be removed by scarifying alone.—*Presse Méd.*, January 15.

A New Streptobacillary Tuberculosis.—Courmont and Tixier have succeeded in isolating and cultivating a special streptobacillus from a peculiar form of tuberculosis consisting of a hemorrhagic arthritis of the elbow with typical tuberculous manifestations, nodules, giant cells, etc. It was impossible to find the Koch bacillus, but animals inoculated with the serous fluid from the joint succumbed with extreme rapidity to tuberculosis, resembling in some respects the human lesions. In the tubercles on the liver of one of the guinea pigs that had succumbed, a streptobacillus was discovered which cultivated easily on various media, and was reinoculable, producing the specific infection, distinguished by the rapid invasion of the ganglia, the local suppurations in some cases, and frequent hemorrhagic lesions.—*Gaz. d. Osp. e d. Clin.*, January 6.

The Painful Dysphagia of Tuberculous Laryngitis.—It is important to relieve this condition as it interferes with nutrition, and Courtade has found the insufflation of morphin hydrochlorate, 0.2 to 1 centigram, mixed with sugar of milk, the best analgesic for the purpose. The tip of the tube is placed at the entrance of the larynx, and while the patient makes the sound of a prolonged *ah*, he squeezes the bulb and the powder is evenly distributed. Repeat twice a day. Sprays will sometimes relieve better. He uses a solution of phenic acid, 1 gram; glycerin, 20 grams; water, 300 grams; cocain hydrochlorate, 50 centigrams. The spray is inhaled deeply by the mouth, with expiration through the nose. Local applications are also useful in some cases, of a twentieth solution of resorcin or chlorid of zinc, with or without morphin. He warns against the use of counter-irritants.—*Gaz. d. Osp. e d. Clin.*, January 13.

Tuberculous Pleuritis.—In a recent lecture reported in the *Gaz. d. Osp. e d. Clin.* of January 9, Professor Maragliano remarked that in forming a prognosis of this affection we must banish from our minds the old idea that tuberculous affections were necessarily fatal. Tuberculous pleuritis frequently terminates in spontaneous recovery, especially when the effusion is serofibrinous, but if the effusion does not show a tendency to be absorbed, thoracentesis should be performed, and the ribs resected if necessary. This latter, he adds, is still a problem for the future, as at present surgical intervention is reserved for desperate cases; but, if instead, we strove to prevent the development of an affection by surgical intervention in the initial stages, he believes that this therapeutic conception would demonstrate its utility and be crowned with success in practice, especially in these cases, when the lungs are compressed by the effusion, and fibrous stratification and pseudo-membranous adherences prevent absorption.

Transformation of Human Tuberculosis by Passage Through Cold-blooded Animals.—Intraperitoneal inoculation of dead or living human tuberculosis in fishes, snakes, lizards, turtles and frogs, produced violent phagocytosis reaction, ascitic effusion, false membranes, adherences between the viscera and typical tuberculous granulations. The dead bacilli retained their shape and reaction to stains more than four weeks. The living bacilli adapt themselves to their new environment by the twelfth day, becoming club-shaped, ovoid, dichotomous, etc., showing involution. Some spored; others sent out lateral buds. Far from losing their vitality, these bacilli cultivated readily, producing these transitional forms of Velars' bacillus. Injected into guinea pigs, these transformed cultures produced a much-

attenuated tuberculosis or a local lesion or no reaction, according to the number of passages and the degree of transformation. Lizards resisted the inoculations of human tuberculosis and also proved refractory to Velars' bacillus, bac. tuberc. piscium.—Dubard of Dijon, *Bull. de l'Acad. de Méd.*, December 7.

The Audiffred Prize for the Cure of Tuberculosis. Acad. de Méd. Paris, was not awarded this year. Over a hundred communications were received, mostly from non-medical persons, who announce that on receipt of the prize, they will impart the particulars of an infallible remedy. One contained a poem celebrating the golden wedding of the writer, who had married a tuberculous girl fifty years before, and cured her with his remedy. The only two strictly scientific communications were from America. One from Hirschfelder of San Francisco, who described his success with oxytuberculin (*vide JOURNAL*, Vol. XXIX, p. 208), and the other from Vergara Lope and Herrera of Mexico, reporting the successful results of their treatment of tuberculosis with artificially rarefied air (*vide JOURNAL*, Vol. XXVII, p. 656). Both are interesting, but the Académie does not consider them sufficiently established by experimentation with animals to entitle them to the prize.

Mercury in Tuberculosis.—Dr. Dubois reported to the Paris Académie de Médecine a year ago (*Bulletin*, Feb. 2, 1896), that he had secured results surpassing all expectation, in tuberculosis, with a thousandth solution of the bichlorid of mercury, 0.5 c.c. injected every other day in the subspinal or subclavicular region, increasing to 1 c.c. At first he thought he must have stumbled on syphilitics, but he soon became convinced that this was not the case. He has been using this treatment for five years, and has succeeded, even in advanced cases, in attenuating the night sweats, arresting hemoptysis, and curing the digestive disturbances, but his most remarkable successes were obtained in the earlier stages. He described twenty cases in detail. Tentative treatment in this line has already been made by Rush, Watson, McDowell, Ham and others, and more recently by Miquel and Rueff with mercuric iodid sprays and Grande with sublimate and methylene blue.

Waning Popularity of Koch's Tuberculin.—As to Koch's new tuberculin, the editors of the *Deutsche Medicinische Wochenschrift*, after having devoted considerable space to papers upon the subject, have now resolved to close their columns for a time to its further consideration. It will take years to really decide the therapeutic value of the new serum, and discussion at present can only be illusory, the personal feelings of the observer too greatly influencing his judgment as to results. The use of the old tuberculin for diagnostic purposes seems to be thoroughly disapproved of here in the clinics for internal medicine. The reaction which occurs after the injection of tuberculin when tubercle bacilli are present is considered to be due to a necrosis of tissue around the bacilli and the absorption of toxic products therefrom. Such a septic reaction can not be without danger, and necrosis of tissue may cause the further absorption of bacilli into the lymph or blood vessels and so institute an acute process. As the majority of people have encapsulated bacilli in the apices of the lung or somewhere in the bronchial glands without being in the slightest sense tuberculous, the recurrence of the reaction can not be said to be definitely diagnostic of active tuberculosis. In cases where the bacilli have been completely shut off from the possibility of doing any harm by Nature's protective barriers of inflammatory lymph, there is danger that the quiescent condition may become active under the influence of the injected toxins. The injections are practically considered unjustifiable, except in the determination of the etiology of such serious affections as pleurisy or ascites where the patient's dangerous condition makes an experimental diagnosis with tuberculin less risky.—*Medical News*, October 23.

Products of the Tubercle Bacillus and Serum Therapy.—A. E. de Schweinitz and Marion Dorset have succeeded in isolating the special substance contained in or secreted by the Koch bacillus which causes the necrosis apparently necessary for the progress of the tuberculous infection. It is a definite, crystalline, soluble substance with the chemie formula $C_{12}H_{10}O_4$, which coincides with an incomplete acid of the fatty series, teraconic acid. This substance is found constantly in the culture-fluid, but the bodies of the bacilli only contain traces of it. It produces chills, hypothermia and dyspnea in sound and tuberculous guinea pigs. Injected directly into the liver it produces necrotic foci. After filtering the cultures, the bacilli were washed in cold water, and a hot aqueous extract then made. This extract contained an albuminoid which produced several times in succession the tuberculin reaction experimentally. Koch's first tuberculin ceased to produce any reaction after one or two injections, because it contained the necrosing, hypothermising principle described above, while the albuminoid extracted from the bodies of the bacilli produces the opposite effect. These two principles which seem very active, were both obtained from attenuated cultures. The writers have also succeeded in obtaining experimental immunization (horses) and, by the Brieger Boer method, have secured a grayish powder as a precipitate of the serum of the immunized animals, giving the biuret reaction, which they consider the specific antitoxin, as it produces exactly the same immunizing effects as the serum. Their experiments encourage the belief that as serotherapy becomes perfected we can hope for the day when it will be practicable to apply it to man.—*Presse Méd.*, January 12, from the *Cbl. f. Bact.*, 1897, No. 8.

The Diagnostic Value of Koch's Tuberculin.—Time has elapsed sufficient to allow a quite accurate estimate of the value of Koch's discovery, in its immediate practical bearing upon medical art. No one can deny that, beyond this valuation, there is a reasonable expectancy of great good to be developed later, on the lines laid down by Koch, and especially with regard to other diseases than tuberculosis. In fact, the value of diphtheria antitoxin, which is, in a general sense, to be classed with Koch's products from the activity of tubercle bacilli, is almost beyond dispute. Therapeutically it may be said that the tuberculins from time to time offered, have not justified the claims of their originators, although there is some support for the argument that benefit has occurred in incipient cases. However, it must be remembered that the average patient with incipient tuberculosis, either so-called from clinical observation or well established, has a fair chance of recovery from purely hygienic measures, if he can fight for his life without handicap. Diagnostically, the tuberculin test has been of untold value in veterinary practice, by enabling the early detection of tuberculous sources of milk and beef. The almost unanimous testimony of veterinarians and others who have had experience with this use of tuberculin, is that it is practically infallible. There is a considerable prejudice against the use of tuberculin as a diagnostic measure for human beings. This prejudice is found even among those who had the most glowing hopes of the benefits of tuberculin, though it may, in some degree, represent a reaction due to the disappointment in regard to therapeutic results. Many believe that the use of tuberculin may so depress a patient who is in a weak but not positively tubercular state, that they prefer to leave the decision to the further progress of the case, meanwhile giving the patient the benefit of the doubt by taking all possible precautions against the growth of a tubercular process. Maragliano gives an adverse criticism of Koch's new tuberculin, disputing both the claim that the new product contains active substances not obtainable by the former method of solution with glycerin, and that it is innocuous. Maragliano states that the apparent immunity from bad side-effects is merely due to diminished dosage. How-

ever. Maragliano makes an assertion which may be the germ of an important truth, that it is not necessary to obtain a marked reaction with tuberculin, but that we should use a dose below that required to produce conspicuous phenomena. This is certainly in line with general experience as to medical agents, that the early doses though producing picturesque effects are dangerously large and therapeutically inferior to those which have no obvious immediate result. A recent experimenter has found that some serums or bacillary extracts are not free from living bacteria, and that they are thus a positive source of danger, while others are inert. It is to be deplored that the history of such products is blotted at frequent intervals with the manifestations of a mercenary and commercial spirit, which has extended even to members of the medical profession. Meantime we must admit that the chapter is unfinished, that much is to be hoped for from the labors of numerous scientific investigators at home and abroad, and that what has already been accomplished is of a value which seems small only in the light of the hopes of a revolution in medical practice. It seems to us that one item must be considered in weighing the probable results of combatting tuberculosis with artificial products from its bacilli. The corresponding natural products have no action to prevent a second attack, or to limit the existing attack of tubercular disease; in fact, they decidedly favor the development of further tubercular trouble.—*American Therapist*.

Toxicity of Caseous Patches. Rosa has been investigating the toxicity of caseous tuberculous patches in man, with which he has inoculated thirty rabbits. The results were negative in every instance. The organism therefore has the dual power of killing the bacilli of tuberculosis and of attenuating or destroying the toxic products originating in the bodies of the dead bacilli.—(Italian Cong. of Surgery. *Gaz. d. Osp. e d. Clin.*, November 14.)

New Publications.—The following new monthly journals are quoted among our exchanges: *Hospital Life*, Chicago, devoted to the interests of hospitals, etc.; *Journal of Applied Microscopy*, Rochester, N. Y.; *The North American Journal of Diagnosis and Practice*, St. Louis; *The Wisconsin Medical Recorder*, Janesville, Wis. The subscription price for either of these is \$1 per year.

A General Denial.—The *Medical News* has its little story about drug-giving that has the flavor of one of Dr. Oliver Wendell Holmes' sayings. It runs as follows: "Once upon a time when General Sherman was ailing and under the care of a medical friend of ours for quite a long time, he said, 'Doctor, I do not seem to be getting any better for all your medicines.' 'Well, General,' was the reply, 'perhaps you had better take Macbeth's advice and throw physic to the dogs.' 'I would like to do so, Doctor, but there are a number of valuable dogs in this neighborhood.'"

Three Thousand Dollars for a Sprained Ankle.—At first thought, the supreme court of Minnesota says, it would seem that \$3,000 for what counsel called "a sprained ankle" was much too large. But it believes that "sprains" may often be much more serious than broken bones, and it holds that the evidence in the recent case of *Christian v. the City of Minneapolis* justified a verdict of \$3,000 for the so-called "sprained ankle," and that the damages awarded were not so excessive that it would be warranted in disturbing the verdict.

Effect of the Aldehydes and Ketones on Microorganisms.—Tschugaew states the following conclusions as the results of extensive tests on sixteen varieties of micro-organisms: The toxicity depends upon the aldehydes and diminishes with their increasing molecular weight, and still more when hydroxyl is combined with the aldehyde molecule. On the other hand, if phenyl is combined with the molecule the toxicity is increased, as is also the case with chlorin and bromin. *St. Petersburg Med. Week.*, October 30.

Radiography.—Kelsch found in examination of 124 young persons, none with clinical symptoms of pulmonary lesions, that fifty-one were affected with slight abnormalities, decreased transparency of bronchial adenopathy. He suggests fluoroscopy as a valuable aid in determining the pathologic future of the young. Its importance is evident in eliminating young men with a predisposition to tuberculosis in examining for military service. . . . Vaillant places a sheet of lead between the sensitive plate and its support in radiography of the plevia, which reduces the time of exposure one-half and renders the negative much more distinct. *Bull. de l'Acad. des Méd.*, December 21.

Transplantation of Bones from a Dog.—In 1891 Dubar removed five of the small carpal bones from a ten year old girl with tuberculosis of the right wrist, curetting the ends of the bones of the fore arm and metacarpus, and substituting five pieces taken from the lower end of the femur of an eight day-old dog freshly killed. The wound was sutured and drained; it healed rapidly and perfectly. He never expected to see those bones again, but when he met the patient recently he had a radiograph taken of the wrist, which showed the implanted bones, exactly as first placed, connected by new connective tissue, a third larger in size, and grown into the metacarpal. The joint is movable, painless, and no inconvenience is experienced in sewing or knitting. The favorable results secured should encourage others to follow the same plan.—*Bull. de l'Acad. de Méd., Den. Med. Week.*, December 23.

Experimental Immunization with the Cellular Extracts of Bacteria.—Further experimentation is reported with Büchner's process of mechanical trituration of bacteria with granite sand, compressing the mixture under high pressure, and obtaining thus the cellular extract, the plasmin of the microbes. Positive results were secured with cholera and typhus plasmin. Guinea pigs injected presented the same lesions as if they had received intraperitoneal injections of the living bacilli, and with repeated doses were rendered immune to infection from a ten-fold fatal dose. The results were negative with staphylo- and anthrax plasmin. Of the seventeen guinea pigs injected with tuberculosis plasmin, five are still living. The rest succumbed, although not until long after the control animals. It was found innocuous administered to tuberculous individuals, but the doses were necessarily too small to accomplish the results obtained experimentally.—*Presse Méd.*, December 11, from *Muench Med. Week.* of Nov. 30, 1897.

Special Delusions as Defenses.—If the defendant had certain special delusions which completely possessed him, but was perfectly sane on all other subjects, as was contended in the case of *People vs. Hubert*, then he must, the supreme court of California holds, December, 1897, be judged as though the facts with respect to which the delusions existed were real. Of course, if no partial insanity existed, intimate acquaintances could know nothing of it, and the fact that they did not would be some proof that the defendant had no such delusions, which, the court holds, would render evidence of that character admissible. But matters of science, such as the pathology of mental diseases, the court declares, are always to be proven, and are treated as matters of fact, with regard to which the trial court should not instruct the jury. The fact that these matters are discussed in legal treatises or judicial opinions, it adds, does not convert them into propositions of law, though in some other jurisdictions there is not the same objection to such instructions. The supreme court further maintains that it must be held that conceding that the act was the offspring of an irresistible impulse, and the impulse was irresistible because of mental disease, still the defendant must be held responsible if he at the time had the requisite knowledge as to the nature and quality of the act, and of its wrongfulness. It declares it an impracticable rule which would leave it to the

jury to say whether the act was the offspring of insanity; meaning, whether the defendant would have committed the act had he not been insane. It says that there are many degrees in mental unsoundness, and, however slight the defect, only Omniscience can say whether the act would have been committed had the taint not existed.

The Coia Rolls of the Baron's Blood.—Not long ago one of the distinguished clinical professors was summoned to the house of the Austrian member of the famous banking family of Rothschild. He was accompanied by a younger member of the profession who, while his chief was making the general clinical examination, proceeded to examine the baron's blood. The banker was extremely interested in the procedure, and when the examination was concluded asked what he had found. The assistant replied that he had found everything perfectly normal and healthy; that there was the usual number of red blood corpuscles, showing no marked differences in size or shape, and there was a very normal tendency to the formation of rouleaux. The distinguished patient, who is well acquainted with the hereditary failing of his family in the matter of successfully forming money rouleaux, but who did not realize that this tendency was so outspoken that it could be discovered on microscopic examination of his blood, was very much amused. He was at first inclined to consider the expression as not quite serious, and as meant to stave off questions on the part of an inquisitive patient. When assured, however, that the description was eminently scientific, his admiration for the "new medicine" was correspondingly increased. "What is bred in the bone, will out in the blood" I suppose received a striking exemplification for him. When the visit was over and the doctors were leaving, the fee the younger man found in the envelope handed him by the baron's secretary was not smaller for his chance excursion all unwitting into the atavistic peculiarities of the Rothschild family in his perfectly commonplace description of the results of a blood examination.—*Medical News*.

Therapeutic Ferments and "Local Diabetes."—"Animal life is fermentation. Normal fermentation is health; abnormal is disease. . . . It is possible to substitute a healthy fermentation for a morbid." Proceeding from these premises Backer, Charlier and Bruhat have been applying the typic ferment, *saccharomyces cerevisia*, to the treatment of tuberculosis and cancer since 1892, and reported at the Moscow Congress that they have obtained many cures or remarkable improvement in both diseases, selecting severe cases for the tests. The ferment is injected subcutaneously in small doses, and during treatment the diet is extremely rich in glycogenic substances and starches. Sixty cancerous tumors thus treated have resulted in eighteen cured for several years. In one case of multiple tumor formation the disease was arrested for ten months. In tuberculosis, 75 per cent. were cured, or notably improved, half of them cases hitherto supposed fatal. Backer stated five years ago that a probable explanation of the sterility of some women was a lack of glycogenic elements in their uterus, which seems to be confirmed by Brault's announcement that the glycogenesis in a neoplasm is in exact proportion to the rapidity of its development (*vide JOURNAL*, Vol. 28, page 1093). Backer has also noted the fact that the glycogenic organs are the chosen seat of neoplasms and calls cancer "local diabetes." The subcutaneous injection of pure ferments transforms the glycogenic substances into alcohol and its subproducts, which he believes have a neutralizing power in the nascent state.—*Journal d'Hygiène*, October 21.

Suprarenal Extract in Menacing Death from Chloroform. Dogs were chloroformed until the circulation and respiration ceased, and then in thirty seconds injected with 1 to 2 grams of a 1 per cent. suprarenal extract, in the vena jugularis, restoring them to life. Intravenous injections were found the most effective. The powerful effects obtained even with these small

amounts prove that the substance is not innocuous and should be limited to small doses. Mankowski therefore recommends that freshly prepared, sterilized, suprarenal extract should be at hand at every chloroform narcosis, to use promptly in case of menacing danger, adding that the best results are attained by combining the intravenous injection of the extract with simultaneous massage of the heart and subcutaneous infusion of salt solution.—*St. Petersb. Med. Woch.*, October 30.

Overworked Pharmacists in New York.—A bill in the New York legislature has for its object a shortening of the hours of labor of druggists' assistants. The bill provides that no pharmacist, drug clerk or other employe in a drug store in the city of New York shall work more than ten hours a day on week days, excepting Saturdays, when the time shall be twelve hours. On Sundays and legal holidays the time shall be six hours. All such employes are prohibited from sleeping in any store, room or laboratory where drugs are stored or compounded, the Board of Health is to enact rules and regulations governing the enforcement of the law. The bill has been prepared at the request of some of the druggists and drug clerks in the borough of Manhattan. So far as is known there has been no action in other localities among either the druggists or their clerks. The bill as it was introduced is not so radical as it was at first intended that it should be. Some of the Manhattan drug clerks wanted a bill presented that would make necessary the closing of drug stores at certain hours of the day as well as on Sundays. This bill was thought to be too drastic, and the measure as introduced is a compromise.

Gleanings.—Dysentery successfully treated with three rectal injections of antipyrin a day, 5 grams to 250 grams water, retained fifteen minutes. *Semaine Méd.*, October 27.—Fresh air cure successfully applied to various protracted and subacute infections of childhood, hereditary syphilis, whooping cough, chronic gastro-intestinal affections, etc. *Thérapeut. Woch.*, November 14.—Bruns' airol paste found extremely beneficial in ophthalmology, substituting linim. exsicc. Pick, for the mucilage. *Vide JOURNAL*, Vol. xxix, page 34.—Examination of the anus facilitated by inserting the finger in the vagina, the patient in the decub. dorsal. with pelvis elevated.—The blood of diabetics decolorizes methylene blue solution even after all traces of sugar has disappeared from the urine. 20 cm. blood to 1 c.c. methylene blue, 1 to 6,000 solution. *Deutsche Med. Woch.*, November 25.—The lypolysis in mixtures of blood and chyle through which air has been conducted for twenty-four hours, results in the production of a diffusible substance that dissolves in water, the nature of which is still undetermined. *Ibid.*—Systematic alimentation with collagenous substances supplementing a good general diet found effective in promoting healthy growth of hair-covered surfaces. Suggested also as beneficial in arteriosclerosis. *Gaz. Med. Liège*, November 25.—Fourth case on record of diphtheroid syphilis simulating true croup. Cured with specific antisyphilitic treatment. *Journ. des Sc. Méd. de Lille*, November 20.—Prompt cure of eczematous external otitis with ten-minute baths of warm 0.5 per cent. solution of sodium fluorid.—Kühnau announces the negative results of the examination of 169 patients to determine the clinical and diagnostic value of bacteriologic investigation of the blood. *Ztschrft. f. Hyg. u. Inf.*, No. 3.—Remarkable success of ichthyol in two cases of chyluria; one, hematochyluria filariensis. One-half to two grams a day in pills. *Therap. Woch.*, December 12.

The Library of the Chicago College of Physicians and Surgeons.—This library was begun in a serious way in August, 1895, when a trained librarian was engaged, and the books belonging to the library were classified, accessioned and catalogued. The Dewey decimal classification was used and has proved adequate for this small collection. The library has grown by donations from the friends of the college, and a few small purchases,

til now it numbers 1,752 bound volumes. In addition to these, unbound volumes and reprints bound in pamphlet cases fill shelf room enough to hold 2,500 bound volumes. The accessions during the year have not been large: 292 bound volumes and about 2,000 journals. Twenty-seven medical journals are received regularly. The bound literature is carefully indexed by author and subject, part of it analytically. There are about 4,000 cards in the catalogue. The average number of students using the library each day has increased from twenty-six during 1896, to forty a day during 1897. Several classes do library investigation. At present the textbooks and medical journals are the most used. The more recent books are put on reference shelves and are always accessible to the students for comparison and reference. The librarian will promptly acknowledge the receipt of any donations which the friends of the college are willing to give. Reprints are especially desirable, each one being treated in the catalogue as a book. The librarian is especially anxious to secure the following serials: *American Journal of Medical Sciences*, Vols. 1-22 inclusive, and years 1893 to date; *Annals of Surgery*, Vols. 1, 2 and years 1893 to date; *Boston Medical and Surgical Journal*; *Edinburgh Medical Journal*, 1828 to date; *Lancet* (London) 1835 to date; *New York Medical Journal*, Vols. 1-47, 56-59, 61-2; *New York Medical Record*; *Therapeutic Gazette*, Vols. 1-3. Although these are needed to help complete one department of the library, any medical literature is acceptable. The library has a large number of valuable duplicates which are for exchange with other libraries or private individuals, a list of which can be obtained on application at the library. The library room has recently been decorated with some very fine photographs of medical men.

Address, THE LIBRARIAN, College of Physicians and Surgeons, 813 W. Harrison St., Chicago.
Louisville.

PHYSICIANS' RIGHT OF WAY.—An ordinance has been passed by the Common Council and is now in effect in Louisville, regulating the rights of way and permits therefor. Section 1 concerns the right of way of ambulances over any other conveyance, etc., while engaged in going for or conveying any sick and wounded. Section 2 concerns the wearing of physician's badge and the right of way granted such badge. Section 3 has to do with the issuance of permits to practice medicine. Section 4 requires the health officers to obtain a certified list of physicians licensed by the State Board of Health and practicing in Louisville, etc. Section 5 prohibits greater delay than five minutes to ambulances, etc., at railroad crossings, etc. Section 6 provides penalties for offenses against the ordinance.

STATE MEDICAL COLLEGE.—The Hon. J. H. Lackey of Trigg County has introduced a bill into the Legislature which provides for a free medical college in connection with the State Agricultural and Mechanical College at Lexington, Ky. The author of the bill contends that many young men are deterred from taking a course in medicine because of the fees, that there are free schools for nearly all trades, arts, sciences and professions except that of medicine, and that the conditions are favorable at present, without extra expense in regard to the buildings, to establish a medical school in connection with the above College. The bill states that as there is already taught in the College the following branches, chemistry, anatomy, physiology, botany, zoology, histology and microscopy, there would only be required the addition of surgery, theory and practice of medicine, materia medica, obstetrics and demonstrative anatomy. It provides for the establishment of the additional branches and that the course of study leading to the degree of M.D. be provided for as one of the courses of the College, and that a sum of money not to exceed \$10,000 be appropriated for the purpose. Under its provisions each county in the State is entitled to place and maintain as matriculates in the school,

two properly prepared young men or women, free of charge for fees during the time necessary to complete the course of study required. Appointments are to be made upon competitive examination by the board of health of the respective counties. Examinations shall cover the requirements for entering the freshman class of the College. Appointments shall be open to both sexes and the examinations held at a convenient place in each county at a date not later than September 15 of each year. The Faculty of the College shall be elected by the State Board of Health, subject to the approval of the Trustees of the Agricultural and Mechanical College, who shall have control of the management of the medical school. No professor shall be removed without the consent of the State Board of Health. It is provided that the \$10,000 shall be paid the Treasurer of the Agricultural and Mechanical College upon the passage of the bill, and used by the Board of Trustees to establish and maintain a high grade medical college. Immediate steps are to be taken to have the medical department ready for the reception of pupils by Oct. 1, 1898. Provision is made for the occupancy of any unused buildings or rooms at the College as at present, and for the building of additional buildings as the growth of the medical department will warrant.

ABORTION.—In the Senate, Mr. Petrie of Todd County introduced a bill to prevent criminal abortion and to punish those guilty of this offense. This bill is introduced as a result of vigorous work on the part of the Kentucky State Medical Society, through a special committee appointed for that purpose, and through the State Board of Health, by its able secretary, Dr. J. N. McCormack. Under the present law it has never been possible to obtain a conviction because of technicalities, and prosecution can only be instituted in case of death of the mother. It is greatly to be hoped that this bill will pass.

MATHEWS.—Dr. Jos. M. Mathews is in Pittsburg this week as the guest of the local medical society, before which he delivered the annual address.

Detroit.

AT A REGULAR MEETING of the Detroit Medical and Library Association, January 17, Dr. Don M. Campbell read a paper entitled "Headaches." In substance he spoke as follows: The subject is far reaching and has a bearing on the two great wings of medicine, viz., surgery and internal medicine, as well as upon all the various specialties. Considered in a broad and general way the most practical division of the subject from an anatomic standpoint is to consider headache as either intra- or extracranial. In the intracranial headache the variations of the intracranial circulation and pressure are the points of pathologic importance, whereas in the extracranial varieties the variations of pressure are not of so much importance, but a consideration of the various causes of reflex irritation together with that class of constitutional maladies of the rheumatic and gouty types has especial significance. There is no absolutely fixed demarcation between these two forms as they run the one into the other along the line of the neuralgias of the trigeminal nerve. On the one hand a reflex irritation may travel along the intracranial recurrent branches of the trigeminal and be intracranial, and likewise an intracranial lesion may manifest itself by pain reflected over the extracranial branches of the same nerve. Clinically headaches are organic or inorganic; by the former being meant those cases originating in an organic extracranial lesion, viz., meningitis, cerebral tumor, cerebral abscess or tubercular infiltration, etc.; by the latter, all the reflex headaches and neuralgias and the diathetic, toxic, febrile, neurasthenic and hysterical varieties. In the latter varieties of headache the most important thing to determine is whether or not the headache be reflex in its character or whether it have its etiologic factor in a disturbance of nutrition.

THE ANNOUNCEMENT that Dr. S. P. Duffield intends to resign as Commissioner of Health for the city of Detroit will be received with deep regret by the profession. Dr. Duffield assumed the duties of his position in agitated times and has exemplified the possession of that admirable gift of carrying in his right hand, gentle peace, and has demonstrated its power to silence envious tongues. During his term of office the sani-

tary affairs of the city have been conscientiously and capably administered. Dr. Duffield will carry with him to whatever field of labor he repairs, the good will and approval of his professional friends.—*Medical Age*.

HEALTH REPORT for week ending January 15: Deaths 79, under 5 years 30. Births, male 30, female 34: contagious diseases diphtheria 17, scarlet fever 49: deaths from diphtheria 3, scarlet fever, none.

Societies.

The following meetings are noted:

- California*.—San Luis Obispo Medical Society, January 14.
Connecticut.—Windham County Medical Association, Hartford, January 18.
Illinois.—Brainerd District Medical Society, Mason City, January 27; Chicago Medical Society, January 26; Physicians' Club of Chicago, January 31.
Indiana.—Marion County Medical Society, Indianapolis, January 18; Montgomery County Medical Society, Crawfordsville, January 18; Purdue Pre Medical Society, Lafayette, January 14; St. Joseph County Medical Society, South Bend, January 25; Tippecanoe County Medical Society, Lafayette, January 17.
Iowa.—Blackhawk County Medical Convention, Waterloo, January 14; Council Bluffs Medical Society, Glenwood; Jasper County Medical Association, Newton, January 18; Polk County Medical Society, Des Moines, January 11; Sioux Valley Medical Association's semi annual convention, Sioux City, January 21.
Kansas.—Golden Belt Medical Association, Solomon City, January 13; Leavenworth County Medical Society, Leavenworth, January 13.
Kentucky.—Kentucky Midland Medical Society, Shelbyville, January 13; Paducah Medical and Surgical Society, January 19.
Maine.—Maine Academy of Medicine, Portland, January 10.
Maryland.—Johns Hopkins Medical Society, Baltimore, January 18.
Massachusetts.—Hampden County Medical Association, Springfield, January 17; Hampshire County Medical Society, Springfield, January 12; Millers River Medical Society, Orange; Worcester District Medical Society, Worcester, January 12.
Minnesota.—Southwestern Minnesota Medical Association, Worthington, January 11.
Missouri.—Kansas City Academy of Medicine, January 11; St. Louis Medical Society of Missouri, St. Louis, January 22.
Nebraska.—Lincoln Medical Society, January 11.
New Hampshire.—Center District Medical Society, Concord, January 11.
New Jersey.—Burlington County Medical Society, Mount Holly, January 18.
New York.—Albany County Medical Society, Albany, January 19; Binghamton Academy of Medicine, January 18; Chenango County Medical Society, Norwich, January 11; Duchess County Medical Society, Poughkeepsie, January 12; Dunkirk and Fredonia Medical Society, Dunkirk, January 19; Elmira Academy of Medicine, January 12; Jefferson County Medical Society, Watertown, January 11; Kings County Medical Society, Brooklyn, January 18; Newburgh Bay Medical Society, Newburgh, January 11; Oneida County Medical Society, Oneonta, January 25; Ontario County Medical Society, Canandaigua, January 11; Practitioners' Society, Rochester, January 13; Ninety-second annual meeting, of the Medical Society of the State of New York, Albany, January 25, 26 and 27; Syracuse Academy of Medicine, January 11; Wayne County Medical Society, Newark, January 18; Westchester County Medical Society, Mount Vernon, January 18.
Ohio.—Clark County Medical Society, Sandusky; Cleveland Medical Society, January 14; Dayton Academy of Medicine, January 24; Eastern Ohio Medical Association, Toronto, January 11; Lorain County Medical Association, Lorain, January 11; Lucas County Medical Society, Toledo, January 7; Mercer County Medical Society, Greenville, January 16; Muskingum County Medical Society, Zanesville, January 13; Toledo Medical Association, January 14.
Oklahoma.—Central Oklahoma Medical Association, Enid.
Pennsylvania.—Allegheny County Medical Society, Pittsburgh, January 18; Beaver County Medical Society, Beaver Falls, January 13; Berks County Medical Society, Reading, January 11; Blair County Medical Society, Altoona, January 20; Bradford County Medical Society, Towanda, January 11; Cumberland County Medical Society, Carlisle, January 11; Delaware County Medical Society, Chester, January 12; Lebanon County Medical Society, Myerstown, January 11; Lehigh Valley Medical Association, Easton, January 25; Luzerne

County Medical Society, Wilkesbarre, January 12; West Branch Medical Society, Sunbury, January 11.
Wisconsin.—Dodge County Medical Association, Beaver Dam, January 10; Fox River Medical Association, Green Bay, January 28.

CHANGE OF ADDRESS.

Bradford, H. W., from Boston, Mass., to 120 Paul Gore St., Jamaica Plain, Mass.
 Burchard, T. H., from 53 W. 53d St. to Buckinghau Hotel, New York.
 Clausen, J. J., from New Ridge Building to 501 Rialto Building, Kansas City, Mo.
 Cox, G. W., from 2255 Wabash to 2945 Groveland Ave., Chicago, Ill.
 Dargatz, D. G. G., from Ridge Bldg. to 4 E. 10th St., Kansas City, Mo.
 Ewing, W. B., from Canonsburg to 515 Penn Ave., Pittsburgh, Pa.
 Furay, C. E., from Chadron, Neb., to 2237 Seward St., Omaha, Neb.
 King, Thomas, from Piqua, Ohio, to West Mansfield, Ohio.
 Kay, T. W., from 206 Penn Ave., to Scranton Private Hospital, Scranton, Pa.
 Louis, I. C., from 354 Tremont St. to 210 Huntington Ave., Boston, Mass.
 May, L. F., from 191 Fullerton Ave. to 910 Irving Park Boul., Chicago.
 McBride, J. H., from Hartland, Wis. to Pasadena, Cal.
 Stockton, Sarah, from 227 to 413 N. Delaware St., Indianapolis, Ind.
 Woodward, J. H., from Burlington, Vt. to 58 W. 40th St., New York.
 Woodward, A. P., from 21 Powell St. to 1228 Sutter St., San Francisco, Cal.

THE PUBLIC SERVICE.

Notice.—An Army Medical Board will be in session at Washington City, D. C., during the month of May, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 15, 1898, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character and habits. The candidate must be between 22 and 29 years of age, and a graduate from a Regular Medical College, as evidence of which, his Diploma must be submitted to the Board.

Successful candidates at the coming examination will be given a course of instruction at the next session of the Army Medical School, beginning in November, 1898.

Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

GEO. M. STERNBERG,
 Surgeon-General, U. S. Army.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from January 8 to 14, 1898.

First Lieut. Irving W. Band, Asst. Surgeon, is relieved from duty at Ft. Huachuca, Ariz., and ordered to Ft. Du Chesne, Utah, for duty.
 First Lieut. Charles E. D. Flagg, Asst. Surgeon, is relieved from duty at Ft. Du Chesne, Utah, and ordered to Columbus Bks., Ohio, for duty.
 Capt. H. C. Fisher, Asst. Surgeon, is granted three months and two days' leave, to take effect on or about Feb. 1, 1898.
 Capt. Henry A. Shaw, Asst. Surgeon, will report in person at Ft. Crook, Neb., for temporary duty at that post, and upon the arrival there of First Lieut. Deane C. Howard, will return to his proper station at Ft. Snelling, Minn.

THE HISTORY AND DIAGNOSIS OF A CASE OF CARCINOMA OF THE STOMACH AND THE FIRST OPERATION OF EXCI- SION OF THE STOMACH IN AMERICA.

BY HUGO SUMMA, M.D., AND A. C. BERNAYS, M.D.

HISTORY OF THE CASE AND DIAGNOSIS.

By HUGO SUMMA, A.M., M.D., Professor of Pathology and Clinical Medicine at the Marion-Sims College of Medicine, St. Louis, Mo.

The patient was Mr. Conrad Beck, 42½ years old, a German, machinist, married, and the father of four children. The anamnesis shows a very good family history. The patient's mother is still living, while his father died of senile marasmus. All of his brothers and sisters are in good health and there is no inclination to diseases of the stomach in any member of the family.

The patient has always enjoyed good health, with the exception of an attack of measles when a boy. Does not remember any trauma, either in the region of the stomach or in any other part of his body.

In the early part of June 1897, the patient noticed pain in the region of the stomach, particularly severe soon after eating, and also a somewhat impaired action of the bowels amounting to constipation. Both of these symptoms appeared somewhat abruptly. About three weeks afterward, on June 25, 1897, he had four gastric hemorrhages within a day and a half. The blood was light red without admixture of air. Dr. Louis H. Davis, who attended him at that time, estimated the amount of blood lost at one and one-half gallons. In the early part of July, I was consulted for the first time in the case. The symptoms at that time were chiefly subjective. He complained of pain, which was increased during digestion, in the region of the stomach, and also of pain on pressure near the junction of the cartilages of the eighth and ninth ribs of the left side. There was at no time an impairment of the appetite nor any vomiting, but there was obstinate constipation. No tumor was visible or palpable.

After a thorough deliberation, in which the differential diagnosis between cancer and round ulcer was carefully considered, a decision in favor of round ulcer was made and Leube's treatment was instituted. The severe hemorrhages preceding the first consultation seemed to preclude the investigation of the case by means of test meals. It was a reasonable expectation to clear up the diagnosis *ex juvantibus* by the Leube treatment, but this proved to be the misleading feature and for three months obscured the clinical observation of the case. Leube himself lays great stress upon the value of his method of treatment as a means of confirming a doubtful diagnosis of *ulcus rotundum*; in fact, he says that the favorable result

of the treatment justifies a conclusion in favor of the positive existence of an *ulcus rotundum*. Boas considers the same conclusion justifiable when his method of treatment is beneficial in the same kind of a case. His treatment consists in gradually increasing doses of nitrate of silver. This method was applied after the case was turned over to my exclusive supervision, in November, and was followed by even better results than Leube's treatment, which had undoubtedly benefited the patient during the months of July and August.

After a second consultation in September, Fleiner's treatment was tried, because on account of the beneficial results obtained by Leube's treatment we were under the impression that the case was one of round ulcer. The Boas treatment, which was tried in November, was followed by the most encouraging improvement, but December 24 a gradual recurrence of the old symptoms was noticed.

It now seemed justifiable to risk the introduction of the stomach tube and this was done every day for two weeks beginning December 26. Through the tube, Ewald's test-breakfast or Riegel's test-meal was expressed for the purpose of gaining a knowledge of the motor, secretory and digestive functions of the stomach.

The result of these gastranalyses was always the same. The total amount expressed never exceeded 20 c.cm. Free hydrochloric acid was never present, nor was there any lactic acid. The total acidity varied between 10 and 20 per cent. Yeast fungi and sarcinae were absent and only very few bacteria were found by microscopic examination. Remnants of meat and starch, well advanced in digestion, occurred and red and white blood corpuscles were found in the same relative proportion as in the blood in each specimen of the stomachic contents that were examined microscopically. Toward the end of the expression of the contents, a very slight hemorrhage was noticeable macroscopically but no trace of tissue could ever be detected.

After carefully weighing the symptoms that presented themselves in this peculiar case there were left three points that appeared more in favor of carcinoma than of ulcer. These were permanent absence of hydrochloric acid, no vomiting and the age of the patient, while the remaining symptoms could be explained as well under the assumption of ulcer as of carcinoma.

The patient had lost twenty-seven pounds in weight during seven and one-half months. There was a cachectic appearance gradually becoming apparent, while the anemia seemed to be disappearing when judged by the visible mucous membranes.

Based upon these carefully observed facts a final diagnosis was made of ulcerated cancer of the stomach located between the cardia and the pylorus. The patient was then sent to Prof. Bernays for an explora-

tive section with a view of possibly removing the affected tissues.

THE OPERATION OF EXCISION OF THE STOMACH.

By AUGUSTUS CHARLES BERNAYS, A.M., M.D., Professor of Anatomy and Clinical Surgery at the Marion-Sims College of Medicine, St. Louis, Mo.

It has been known for years that the entire stomach can be successfully removed in dogs, and that these animals remain alive in perfect health for years. The best known case is the Czerny dog who lived over five years without a stomach and was then in perfect health when killed for the sake of a scientific experiment. Portions of the stomach have been successfully excised in cancer cases by over 150 surgeons. The parts removed involved from one-tenth to eight-tenths of the organ. The entire stomach was successfully removed from a female patient aged 53 years, at Zurich, by Dr. Schlatter. Six months after the operation the woman had gained twelve pounds in weight and is now in good general health.

In all cases that have ever been operated upon suffering from cancer of the stomach, the exact portion of the stomach which was to be removed was determined after the abdomen was opened. It is practically impossible to predict in any case the operation which must be performed. I have usually preferred palliative gastro-enterostomy to a partial excision of the stomach and in some cases have been satisfied to merely curette away the masses of neoplasm which were found obstructing the pyloric orifice.

There is no doubt in my mind after an experience of more than seventy palliative operations that these measures have been of benefit to the patients in prolonging life and in alleviating pain. In some cases the results were simply wonderful. I saw a patient upon whom I had done a gastro-enterostomy gain thirty-five pounds in weight in about two months and another from whom I curretted away over a pound of tumor-mass within the stomach, gained twenty pounds in one month. Both patients died within the year from the continuation of the carcinomatous cachexia and the continued growth of the neoplasms. Palliative operations in cancer cases are never indicated when a radical and scientific operation can be performed. For instance in cases of cancer of the breast and in uterine cancers which come to us early enough we no longer remove the tumor alone, but always the whole organ. We are not justified in merely removing the whole of the diseased organ, we must also remove the lymphatics leading away from the organ as completely as possible. I invariably do this radical operation in cancers of the breast and also of the womb. In the latter class of cases I have abandoned the old vaginal hysterectomy in favor of the operation of removing the broad ligaments and the womb through the abdomen. My mortality in the latter operation is less than 10 per cent. and no doubt will continue to decrease with a larger experience and a better technique. The length of time that patients remain free from a return is certainly much increased and there is a chance for a radical cure.

No kind of cancer is more certainly fatal than cancer of the stomach, and if the operation of gastrectomy can be successfully performed it must be done early and before the cachexia has brought the patient to the brink of the grave. As in other organs the total removal of the stomach is the proper operation in incipient cases. In fact, there can scarcely be a

doubt in the mind of any medical man that if an excision of a cancer of the stomach is to be made at all it ought to be a total excision. Partial excisions must be abandoned, and in fact have been abandoned in favor of gastro-enterostomy, curettement or some other merely palliative measures of treatment. I have not done a pylorotomy for over three years and I find that the Germans have almost abandoned the partial resections of the stomach in favor of palliative measures.

The future treatment of incipient cancer of the stomach will be the total or nearly total excision of the organ. Our plain duty is to work toward a perfection of the technique of this operation. My object in reporting the following fatal operation is to add what I have learned to the very meager stock of information we have about this new operation and to make some suggestions tending toward an improvement of its technique.

The patient, whose clinical history is detailed by Prof. Hugo Summa, entered the Rebekah Hospital Jan. 9, 1898. He was carefully prepared for the operation of celiotomy in the usual way, by baths, a purge and antiseptic pack, and by a properly restricted diet. The operation was begun January 11 at 9 A.M. and primarily consisted in an explorative abdominal

Fig. 1.—Diagram of horizontal plane at tenth dorsal vertebra. Distance from esophagus to pylorus shown in a normal case and is about one-fifth the length of the major curvature, usually not more than five inches.

section in the median line between and extending from the ensiform process to the umbilicus. The hand having been introduced and made to explore the entire surface of the stomach, detected a hard umbilicated irregular tumor involving the entire minor curvature of the stomach excepting about one inch of the pyloric end. There were only three small indurated lymph glands, and they were situated near the major curvature of the stomach in the omentum majus. The whole mass was freely movable, except where it was bound down to the pancreas by adhesions. There were no symptoms of obstruction and, in fact, the pylorus was normal. The operation of gastro-enterostomy was thus plainly contraindicated and the only thing to be done was a removal of the cancerous growth. I hesitated, but the conclusion that the extirpation of the diseased organ was the only rational thing to do was inevitable and I proceeded with the operation. The first step was the transverse section of the pyloric extremity of the stomach, one inch from the duodenum. I next closed the two orifices made by the cut by means of clamps. The duodenal end was drawn out of the abdomen and

placed upon the right side of the abdomen entirely out of the way. A large plug of gauze was inserted into the pyloric stump to prevent the escape of intestinal contents. The freeing of the posterior wall of the stomach from its adhesions to the pancreas was next done and was a piece of difficult dissection. I next ligated and cut off the stomach from its omental connections along the major curvature to the fundus. At this time, while drawing the fundus out of the cavity in order to ligate and cut off the gastro-splenic vessels and ligaments, a small quantity of gastric contents escaped, but was caught to a great extent upon pieces of gauze that were kept in readiness. The stomach was now free from all its connections excepting the minor curvature and the esophagus. There had been no hemorrhage of any account up to this time, as nearly all the vessels were tied before being cut. The entire operation was free from dangerous hemorrhage.

The separation of the minor curvature from the crura of the diaphragm, the aorta and the structures lying in front of the vertebral column was difficult only on account of the depth of the cavity, the necessity of operating in a badly illuminated field, so that

Figs. 2 and 3.—These diagrams show the manner and extent to which the stomach was involved in the neoplasm.

the sense of touch was often a more reliable guide than sight. I succeeded in freeing the minor curvature up to the esophagus by means of short clips with the curved scissors. The cancerous growth had shortened the distance between the cardia and the pylorus to about four inches. It was evidently a cancerous ulcer which had a tendency to become scirrhus. The outer surface of the growth was hard, while the inner or mucous surface was ulcerated.

After the entire stomach was freed from all its connections I caught the esophagus with a pair of forceps and cut it across about one-fourth of an inch above the cardia and found a small tongue-like piece of the cancer had grown into the esophagus but had its pedicle in the stomach. I also left a small strip of stomach attached to the esophagus, which I intended to use as a handle by means of which I could pull down the esophagus. This slip proved to be too weak and was soon afterward cut away.

The next step in the operation was the bringing together of the stump of the pylorus and the esophagus. The pyloric stump was freely movable and

easily drawn upward, but the esophagus proved well-nigh unmanageable on account of its elasticity and great tendency to slip away through the foramen ovale of the diaphragm. The toothed forceps with which the assistants pulled the esophagus downward slipped off several times during the suturing which I now began. The method which I adopted of making a direct union between the stump of the pylorus and the esophagus seemed to be easier of accomplishment than the plan which Schlatter adopted of bringing up a loop of the jejunum. There was quite a disparity in the lumina of the esophagus and the pyloric stump, but the esophagus just above the cardia is very lax and dilatable

Fig. 4.—Diagram showing the stump of the pylorus pulled up and esophagus drawn out of the foramen ovale of the diaphragm.

I could easily introduce three fingers without stretching it perceptibly. I have successfully united the ascending colon to the ileum, end to end, and found that the closure was entirely satisfactory. The method I used in this case was simply to make the stitches in the pyloric stump a little farther apart than in the esophagus. The stitches included all the layers of the wall excepting the mucosa. I united the posterior wall first by a series of stitches which were tied upon the mucous side. These stitches united more than half the circumference of the orifices. Next, three stitches were inserted on the lateral aspects. The knots were tied upon the outer surface

of the canal. Lastly, three or four stitches were placed and tied externally upon the anterior aspect of the esophagus and the pylorus. The line of sutures was not as neat as I could have wished, but I was compelled to be satisfied with the work and as I will show later on the stitches held perfectly.

The space which was left after the removal of the stomach was filled out to a large extent by the transverse colon, the splenic flexure and the coils of the jejunum, which sank into the excavation of the diaphragm. I found it necessary, however, to fill up a part of the space by means of a gauze pack. The toilet of the peritoneum was made by means of dry gauze sponges. I use bi-sterilized gauze, made by Johnson & Johnson, of New York, which I found to be absolutely reliable. After the toilet had been most carefully completed I inserted two strips of the gauze, one upon each side of the line of union between the pylorus and esophagus. This was a precautionary measure and was intended to protect the general cavity against infection in case of a leak at the line of sutures. The ends of these two gauze strips as well as the ends of the gauze which lay between the transverse colon and the diaphragm were conducted out of the belly at the upper end of the median incision. The first incision was closed in the usual way up to the point of exit of the gauze drains. A large moist gauze dressing, which was held in place by a binder, was applied over all.

The entire operation had taken two hours and six minutes. Chloroform was the anesthetic used. Silk was used for all sutures and ligatures. An intravenous infusion of physiologic salt solution was made by Dr. Spencer Graves, who together with Dr. Robert E. Wilson and Dr. Frank M. Floyd, rendered me all necessary assistance. At the conclusion of the operation the patient was in fairly good condition; pulse was about eighty and of good volume. There was no pronounced shock, and indeed the patient rallied nicely from the immediate effects of the operation.

The patient was sustained by nutrient enemata and for the first twenty-two hours seemed to remain in the same condition, with the exception of an increased pulse rate, which ranged from 114 to 124 per minute. There seemed to be a fair chance for a successful termination. During the day, however, he grew weaker, complained of thirst and the pulse remained above 120 all the time. His temperature never reached 101 degrees and he succumbed about thirty-six and one-half hours after the operation.

We had no permission to perform a regular autopsy, but my assistants removed the gauze pack soon after death and found that there was no sign of peritonitis and that union between the sutured ends of the alimentary canal, which were in good apposition, was excellent. The cause of death is not quite clear, but I think that the long-continued chloroform narcosis and the impossibility of satisfactorily nourishing the patient, as well as the possibility of the absorption of some escaped stomach contents, must be held to be sufficient to explain the unfortunate result.

In future operations I shall use a rubber tube attached to a silk cord long enough to be passed up through the esophagus and out of the mouth. This tube I will leave in the duodenum, extending from about the beginning of the jejunum to near the opening of the larynx. By pulling it up into the pharynx nutrient predigested fluids can then be injected at regular intervals as may be deemed expedient.

In order to facilitate the suturing between the esophagus and the lower gut, be that the pylorus, the duodenum or the jejunum, I would suggest making the union before the stomach is completely cut off from the esophagus. By this means the esophagus can be pulled down and made accessible. Nearly all of the sutures can thus be inserted before the esophagus is cut off.

Union Trust Building.

THE PSYCHOLOGY AND PHYSIOLOGY OF THE LAYING ON OF HANDS AND OF HYPNOTISM.

Presented to the Section on Physiology and Dietetics at the Forty-Eighth Annual Meeting of the American Medical Association at Philadelphia, June 1-4, 1897.

BY RANDELL HUNT, M.D.

VICE-PRESIDENT OF THE SHREVEPORT MEDICAL SOCIETY AND MEMBER OF THE LOUISIANA STATE MEDICAL ASSOCIATION.

"The smallest hurts sometime increase and rage
More than all art of physic can assuage;
Sometimes the fury of the worst disease
The hand, by gentle stroking will appease."—*Solon*.

Socratic reasoning is being revived, and in the garb of Baconian induction is demonstrating particular truths and predicating general principles that astound even the learned, relegating to their proper place among the relics of barbaric times, intolerance, foolish ridicule, and impotent invective. No longer is the medical profession ready and eager to deride and martyrize a Harvey and a Jenner, nor a French Academy of Science to deny the actuality of meteorites; for science and wisdom walk hand in hand, giving to the world knowledge of universal truths, and power to observe and practice them.

Before man is in a position to take advantage of all these psychic facts that science is in some sort freeing from the mystery that has shrouded them, it is necessary for him to know the attributes and functions of mind, and so to appreciate his own potentiality and to cognize the harmony between individuality and nature. The correlative functioning of upper and lower brains—whether upper or lower—the interrelations of psychology and of physiology, become the matter for most close and searching investigation on the part of the student of the remarkable phenomena that are daily resultant from scientific experiment in the special fields under present consideration. Only by assiduous study of this nature can the scientist equip himself for individual attempt towards the solution of the human-enigma that still presents, despite all that has been achieved, the greatest difficulties and complexities.

The laying on of hands, hypnotism, normal sleep, spontaneous and artificial somnambulism, and dual consciousness, present such similar phases of mind conditions that I will endeavor to describe all as being subject to one general law, that of suggestion.

In doing this, first will be given a history of hypnotism; then sleep will be mentioned, dream consciousness, duality of mind; and finally an attempt will be made to demonstrate that through hypnosis and suggestion the different phenomena may be understood.

The history of hypnotism is as old as the history of the world, for the Chaldean priests, Brahmins and Parsi practiced this mode of treatment, while in China the curing of disease by the laying on of hands has prevailed for ages.

In the "Natural Law of Miracles," written in Arabic 400 years before Christ, not only is hypnotism mentioned, but the different methods of producing it described with an attempted physiologic solution of the psychic attitude. In Egypt friction during ablution was one of the great secret means of treatment, after which the patient rested on skins, and having indulged in prayer, prepared for sleep and awaited visions of Isis. Bernard de Claivaux, a French Cistercian monk, in 1146 said to the Alamannic people: "Ye soldiers of the Christ arise, and hurl down the enemies of the Cross!" Laying his hands on the blind and lame, he healed them, and the grateful people with tears and shouts proclaimed that the saints were with them.

Hippocrates, Aristotle, and Galen knew of the existence of somnambulism, but until Van Helmont and other modern authors recognized and studied the phenomena, no minute or accurate description was ever given of this condition.

Asclepiades of Bithynia obtained great renown as a physician in Rome by curing disease with frictions and the laying on of hands, at times producing by his methods sleep, which sleep he considered very salutary. For hundreds of years the kings of England and France cured scrofula (king's evil) by the touch of the hand, and writers of that time unite in attesting its efficiency.

The first authenticated cures by prayer and the laying on of hands in America were those performed by Alvar Nunez Cabaca de la Vaca, Alonzo dell Castillo Maldonado, Andres Dorantes and Estevanico, an Arabian negro, sole survivors of the unfortunate Narvaez expedition to Florida in the year 1535.

Valentine Graterakes, an Irish gentleman, in 1662, claimed to have had a dream, which he interpreted as a divine revelation, to the effect that he could cure disease by the laying on of hands, and many honorable witnesses bear testimony to his great success. The Lord Bishop of Derry in Ireland, in speaking of Graterakes, says: "I was three weeks together with him at Lord Conway's, and saw him. I think, lay his hands upon a thousand persons; and really there is something in it more than ordinary; I have seen pains strangely fly before his hands, 'till he hath chased them out of the body—But yet I have many reasons to persuade me that nothing of all this is miraculous. He pretends not to give testimony to any doctrine; the manner of his operation speaks it to be natural; the cure seldom succeeds without reiterated touches; his patients often relapse; he fails frequently; he can do nothing where there is any decay in nature, and many distempers are not at all obedient to his touch." Joseph Glanville also speaks highly of Graterakes.

Gassner, an ex-monk, conceived the idea that all diseases were due to possession by the Devil, and that they could be cured by exorcism, the truth of which he first demonstrated among his own parishioners. His cures caused such a great sensation that he went to Elwangen, but finally settled in Regensburg, where at one time he had ten thousand patients. Mesmer's attention being attracted to Gassner's remarkable cures, he went and observed his methods, and in an article afterward makes the important statement that Gassner's processes were in the main identical with his own.

Other instances could be presented showing the efficacy of the laying on of hands, but as the scope of this paper will not permit, I will at once proceed

to analyze sleep and its cognate states, that the psychology and physiology of touch may be made clear.

Since a third of man's life is passed in slumber, it is equally important to physicians to understand thoroughly this condition, that they may the more perfectly appreciate the true relation of man to nature. Sleep is the quiescence of the nerves of sense and of the sensorium. It is more than a mere negation of waking, for it presents a positive side in dream, demonstrating that in this condition certain attributes, functions, and mental activities exist that either do not exist in the waking state, or are below the threshold of sensibility, i. e. of ordinary consciousness. The consciousness of waking is due to the activity of the cerebrum and the nerves of sense, while in sleep there is an inner-waking-dream; and if this inner-waking continues and is exalted, we must look for dream-consciousness in some other part of the brain than the cerebrum.

We have ideas in dreams or we would have no dreams, but as dream-images are confused, they are easily distinguished from the well regulated perceptive images of our waking consciousness, therefore must emanate from some part of the cerebro-spinal system from which we are practically excluded in waking life.

The dreams usually remembered are of a confused character, and ordinarily occur between waking and deep sleep, or between deep sleep and waking; and are insignificant, since they are connected with only a slight displacement of the threshold of sensibility.

A large percentage of dreams are not remembered, and as sense-perceptions seldom if ever pass out of recollection in a few hours, the only physiologic explanation is a different consciousness in the different organs in the dreaming and waking states. Du Prel pertinently says: "Deep dream must at the least depend on the activity of other folds of the brain than those in function while we are awake; possibly of another center altogether. For if we infer the similarity of the organ from that of the consciousness, the dissimilarity of the consciousness would imply the dissimilarity of the organ. And the failure of memory in the case of deep dream can only be ascribed to the want of a common organ with the waking consciousness, the survival of memory between the light dream and waking must result from at least partial community of organ. The withdrawal of the bridge of memory proves physiologically the change of organ, the preservation of the bridge a community of organ; but inasmuch as it is only with the change of an organ of whose nature we know nothing that the significant dream can occur, the logical possibility of the latter must again on this ground be admitted."

We, as physicians, know that this bridge of memory does fail between deep sleep and waking, for sometimes the dreamer will translate his dream into regulated action as in sleep-walking; or into coherent ideas and sound-images as in somnambulism.

In somnambulism difficult problems in mathematics with their intricate complexities are solved, and unless what mind was doing were self-cognized, the perceptions would be as heterogeneous as the confused phantasms of a dream in light sleep. This, however, is not true, for there are numerous authenticated instances in which complicated intellection occurred, Euclidian propositions demonstrated, and even literary works of marked genius composed in slumber. It is well known

that Voltaire wrote poetry in sleep, that Condorcet saw final steps of difficult calculations, and that in this condition Coleridge composed his fragment, "Kubla Kahn."

Whenever a thought, a feeling or a purpose stirs the human mind consciousness is there, whether in a confused dream or in the deepest stages of natural somnambulism; for while the phantasies of a dream may be only imperfectly recollected, the perception, representation, and perfectly constructed ideas of a somnambulist evince true memory directed by purpose.

Helmholtz proved that a definite measure of time was requisite for the transmission of an excitation by the nervous system, and that only a limited number of sensations could be appreciated by the cerebrum in a given period. In narcosis and somnambulism the contrary is easily made apparent, for longer successions of representations occur than the established physiologic limit of time would permit, logically and conclusively proving that the waking consciousness, with its physiologic measure of time is but one form of self-consciousness. Dr. Carl Du Prel assures us, "what is true of the light of the sun is thus true of the light of sense. As the one in its setting and rising neither produces nor destroys the stars, but occasions their optical appearance and disappearance; in like manner the dream consciousness emerges from or retreats into the unconscious, as the sense-consciousness goes down or rises."

To the dual theory of consciousness so beautifully and logically demonstrated by Du Prel, from whose arguments I have largely quoted, I will add in order to make plain and comprehensive one of nature's fundamental laws, Hudson's theory of the duality of the mind.

One phase of mind with its seat in the upper brain, is by Mr. Hudson called objective; the other located in the lower brain, subjective.

The objective mind from its post of observation in the cerebrum takes cognizance of the sense-world through the media of the five physical senses, is the product of man's needs, is under the control of reason and develops what we know as common sense. In man's battle with the material world the objective mind is his prop and staff, and normally is never controlled against reason by another person's suggestion, reasoning as it does analytically, synthetically, deductively and inductively, and refusing to accept anything in opposition to achieved results.

The subjective mind, that of the lower brain (pons, medulla and chord), perceives by intuition independently of the physical senses; is the seat of the emotions, of imagination and of memory, and performs its highest functions only when objective consciousness is in abeyance, manifesting itself most potentially in spontaneous somnambulism and artificial hypnotic somnambulism. In this condition many of the most wonderful functions of the subjective or transcendental mind become manifest, such as reading the thoughts of others even to the minutest detail, and perceiving objects without respect to distance.

The most important and characteristic difference between the two minds is that the objective is never controlled against reason by the suggestion of another, while the subjective is unqualifiedly amenable to suggestion, provided the suggestion is not contrary to previously conceived ethical emotions, an assertion that hypnotism has made an established fact.

In hypnosis the subjective mind accepts every sug-

gestion, no matter how absurd or contrary to objective experience except those suggestions opposed to instinct. It controls all the functions of the body, and also the circulation and the vasomotor system.

The ascendancy of the transcendental or subjective mind over the objective produces the musician, the poet, the artist in any line, and when "exquisitely balanced" with the objective mind, as Mr. Hudson so beautifully shows us, a Shakespeare.

In proof that duality of mind is shown by both anatomy and physiology I may be permitted the same quotation from Surgeon-General Hammond that I made in a former paper on the same general subject.

Dr. Hammond in a paper entitled "The Brain not the Sole Organ of Mind," relates how he removed the brain of a frog and after waiting for the shock to pass put it in water, when it immediately began to swim. He placed his hand so as to stop it and its efforts ceased; taking away his hand it again commenced to swim. Pflüger removed the entire brain of a frog and applied acetic acid to the thigh over the inner condyle. The animal immediately rubbed the spot with the foot of the same side, making a voluntary movement and showing his appreciation of the locality of the irritation. The foot was then amputated and the acid was again applied, when the frog made an ineffectual effort with the amputated member and failing after a few movements rubbed the irritation with the other foot. This experiment with its demonstration of sensation and volition, is certified to by Prof. Austin Flint, who says he has often successfully produced the same phenomenon.

In certain monsters born without a brain, or with important parts of this organ absent, we have interesting examples of the persistence of instinct. "Syme describes one of these beings which lived for six months. Though very feeble it had the faculty of sucking, and the several functions of the body appeared to be well performed. Its eyes clearly perceived the light, and during the night it cried if the candle was allowed to go out. After death the cranium was opened and there was found to be an entire absence of the cerebrum, the place of which was occupied by a quantity of serous fluid contained in the arachnoid." "Ollivier d'Angers describes a monster of the female sex which lived twenty hours. It cried and could suck and swallow. There was no brain, but the spinal cord and medulla oblongata were well developed." "Saviard relates the particulars of a case in which there was no cerebrum, cerebellum, or any other intracranial ganglion. Yet this being opened and shut its eyes, cried, sucked and even ate broth. It lived four days. Some of these movements were reflex, but others were clearly instinctive and adapted to the preservation of life." "But all these instances as well as experiments referred to as having been performed on lower animals, show that instinct does not reside in the brain."

The duality of consciousness and the duality of mind have now been logically proven, but the practical advantages to be enjoyed depend entirely on discovering a psycho-physical method of inducing the transcendental state.

The science of hypnotism aids and furnishes the clue in this investigation by proving experimentally the existence of a stage of hypnosis short of sleep, in which the subjective emergence is sufficiently emphasized for satisfactory therapeutic work. In this specific biologic condition the objective mind is just sufficiently weakened to lose its normal state of con-

trol over the subjective mind; the subject appearing normal, but with an increased susceptibility to impressions through suggestion. All those familiar with hypnotism are aware that by boldly looking a patient in the eyes, and simultaneously suggesting total inability of resistance, he can be made to follow the hypnotist or obediently execute all commands.

A prerequisite factor in successful healing by this psycho-physical process is passivity and faith, a subjective faith, which is only obtainable upon partial or complete cessation of opposition, active and passive, of the waking consciousness. As the transcendental mind is the seat of the cosmic emotions, more than ordinary subjective development on the part of the physician would logically suggest a perfect condition for therapeutic measures, for then the transcendental mind of both would be *en rapport*, and telepathic communication would at once result with relief of pain or the cure of the disease.

Facts in hypnotism demonstrate the complete amenability of the subjective mind to the power of suggestion, making it obvious that any therapeutic suggestion from a physician would prove very efficient if in accord with instinctive auto-suggestion. By analytical reasoning we must infer from this that the subjective condition is essentially restorative, and since normal sleep can be converted into somnambulism, one of the deepest stages of subjectivity, we are again logically forced to admit the similarity of sleep and somnambulism, and that the latter is not due to disease but on the contrary heals directly through deep sleep and suggestion.

Healing the sick in ancient times was supposed to be due to divine aid exerted by means of "prayer, ceremonies, laying on of hands, incantations, amulets, talismans, rings, relics and images, and the knowledge of it was transmitted with the sacred mysteries." Modern science, however, guided by the spirit of truth in the garb of inductive reason, realizes that the lightest or deepest stage of hypnosis is due to a peculiar state of the nervous system induced by certain objective conditions, and like ordinary sleep is dependent upon an absence of sensorial impressions. A knowledge of this lead Brown-Sequard and other neurologists, to show that when one objective or sense-function is used to excess, the others become for the time being inhibited; and that continuous stimulation of one cerebral center would not only result in temporary inhibition of objective cerebration, but would ultimately culminate in a loss of sensorial consciousness and the development of trance or somnambulism.

In sleep the brain is in a state of repose, and as Durham conclusively demonstrates the cerebrum contracts and becomes pale and anemic. This anemia is, however, to be regarded as an accompaniment, and like the vascular state of any active organ, an effect rather than a primary cause.

Paracelsus understood and appreciated the laws of mind, for he said: "Whether the object of your faith be real or false, you will nevertheless obtain the same effects. Thus if I believe in St. Peter's statue as I should have believed in St. Peter himself, I shall obtain the same effects that I should have obtained from St. Peter. But this is superstition. Faith, however, produces miracles, and whether it be true or false faith it will always produce the same wonders." Faith, therefore, is an epitome of the law of suggestion, establishing at once a mono-ideaistic attitude of mind,

removing and making impossible auto-suggestion contrary to the result desired. Belief or faith induces passivity through the prevention of antagonistic auto-suggestion, but is not in itself sufficient for the evolution of the transcendental; for certain psychologic and physiologic processes are involved that necessitate attention with prolonged concentrated effort upon a single point, that inhibitory action may take place through over-stimulation of one sense-function. Thus faith is a potential factor of passivity and mental concentration, indispensable conditions for healing by the laying on of hands, for under these conditions only will the subjective mind rise from below the psycho-physical threshold of consciousness, and stand out boldly in all its manifest power to heal.

Schopenhauer says: "The phenomena under discussion are, at least from the philosophic standpoint, of all facts presented to us by the whole of experience without comparison the most important; it is therefore the duty of every learned man to make himself thoroughly acquainted with them. Then, however, will a time arrive when philosophy, hypnotism and natural science, in the unprecedented progress of all its branches, will throw mutually a light so brilliant upon one another, that truths will be apparent which can only thus be attained."

The great medical association of England and of continental Europe consider the phenomena of hypnotism worthy of close investigation. Every physician should make himself thoroughly familiar with its details, and if after careful and systematic research and experiment he finds it efficient, should employ it in the alleviation of bodily ills.

This can now be done without reproach, for the attitude of the profession is favorable, and the correlative advancement of other sciences precludes the possibility of ascribing supernatural agency to the accomplishment of seemingly miraculous facts.

DISCUSSION.

DR. JOHN A. CUTTER of New York.—Some eleven years ago, my mother was seriously sick with pneumonia. I was called in the night to help my father and in the course of our ministrations; he placed one hand on the small of her back and the other over the heart. He said he was endeavoring to confer force on her. There is such a thing as conferring force from one to another. To go into a room in which a patient is slowly dying, from cancer or some other serious chronic disease, and stay in that room but ten minutes questioning the patient and doing whatever is necessary, with me results in a loss of nerve force or whatever you might call it, which I distinctly realize after leaving the patient. There are people who guide and help one and there are others that irritate and annoy. My father has often said that the secret of success of many physicians of large practice but of very moderate education and scientific knowledge was because of their ability to confer force upon the patient, guide the mind and allow nature a chance to come in and effect a cure.

We might put in as a subdivision of this subject, the conferring of hope on a patient. I know that I have been able to stop pain simply by putting my hand on the place where the pain was. Now, the practical application of this idea is very broad, but I wish especially to call attention to the fact that the professional masseurs do more good by conferring force than by any special method of rubbing, kneading, rolling or twisting of the muscles on which they lay particular stress. I have questioned patients as to their previous experience with masseurs and have learned from them that if they are manipulated in the morning or when the masseur is not tired, the séance will give the patient relief, but if the manipulation is done at night, after the masseur has had a hard day's work, he will not do the patient any good but is liable to do him harm, taking energy from the patient unto himself, because the patient has said that he has been distinctly tired after the rubbing when before he was fairly rested. Now, as scientific men, we should be willing to investigate all these things. Because we can not weigh or measure nerve force, because we do

not know what life is and because we have not the knowledge of the currents of electricity which are probably passing up and down and in and about the body. We must not neglect to learn all we can to give our patients the very best possible.

Dr. NATHAN S. DAVIS—It is true that the curing or attempting to cure diseases by the laying on of hands, prayers, charms, and much of what is now included under the term hypnotism, is of very ancient date. Indeed the further we go back in the annals of time the more exclusively do we find all human ailments attributed to good or evil spirits, gods or goddesses, and their cure sought by mental or spiritual influences. And through all the ages, apparently remarkable cures have been, and still are effected by the agencies alluded to. But I think the paper admits that all the diseases cured by such means were purely functional and not involving structural changes. That the mind of man, or the nerve centers through which mind is manifested, exerts a strong influence over the bodily functions both in sickness and in health every intelligent and observing physician will admit. Excite in the mind, confidence, hope and cheerful expectation, and you increase the depth and fullness of respiration, thereby imparting more oxygen to the blood and more efficiency to all the vital functions. Continuing these mental conditions with correct hygienic surroundings will result in the cure of many chronic functional disorders; while the reverse mental conditions will cause them to remain invalids indefinitely notwithstanding the administration of many drugs.

I think all the phenomena of sleep and those conditions connected with sleep, are much better explained on the supposition that they result from incomplete quiescence of either the sensorium or of some of the nerves of sense, than by any theory of duality of brain and mind. When natural sleep is complete there is no evidence of dreams. But when it is incomplete or the degree of quiescence of the sensorium and of the nerves of sense is unequal, or there co-exists disturbance in some of the excito-motory nerve structures, then we have dreams or some of their allied phenomena. The parts of the brain suggested in the paper as the seat or organ of subjective mental activity and consciousness, i.e., the pons, medulla oblongata and cord have been amply demonstrated both clinically and experimentally to be the primary nerve centers of the vasomotor, respiratory, and other involuntary or excito-motory functions. Those centers are connected by commissures with the cerebral sensorium to which the primary impressions must be conducted to be consciously recognized. If stopped at the primary centers they simply return reflex and excito-motory influences capable of producing many of the phenomena mentioned in the paper; and if we include the numerous excito-motory nerve ganglia or cells on the spinal nerves, and in the cardiac and other internal structures, we can more rationally explain all the phenomena discussed without the assumption of duality of mind or duality of mental brain, than with them.

Dr. RANDALL HUNT—Unless a dual consciousness be admitted we can not hope to explain in a logical and intelligent manner the change in the physiologic measure of time necessary for the transmission of an excitation by the nervous system in the dreaming and waking states. Helmholtz and Fechner have proved this experimentally, consequently any assertion to the contrary has no argumentative value unless sufficient evidence is adduced to invalidate it.

The confused and fantastic content of recollected dreams unquestionably demonstrates only partial inhibition of the cerebral cortex and waking consciousness, but in somnambulism, where complete inhibition occurs, there is no recollection, and if the consciousness of both states was identical, recollection would exist because the subject of consciousness would be the same.

If the psycho-physical stage of somnambulism, dream, hypnotism and waking consciousness were the same, hypnotism, dream and somnambulism would be only a continuation of waking consciousness, and the remembrance of the material and figure of these states would be identical. The fact of a loss of recollection and difference in representation in the states of hypnotism, somnambulism and dreaming, argues a change of consciousness in these states and the normal waking state.

Recollection is essentially intellectual and cerebral, therefore somnambulism forces us to look for the center of true memory either in the sensory ganglia or pons, medulla and cord, or both.

If it is physiologically and psychologically true that the pons, medulla and cord are only reflex centers, we would be logically forced to admit that the cerebrum in sleep, dream, somnambulism and hypnotism responds automatically to impressions, exciting reflex action when the will is in abeyance or can not be exerted. If this were true the hypnotee would be unable to withstand immoral or criminal suggestion which is, according

to Kingsbury, Hudson and Charcot, absolutely contrary to experience and clinical facts.

The eminent physiologist Heidenhain says, "the cause of the phenomena of hypnotism lies in the inhibition of the ganglion cells of the cerebral cortex," and if inhibited they can not act automatically, or otherwise, logically and physiologically suggesting another consciousness with its seat in a different part of the brain.

Prof. Laycock and Gall assert that emotion and instinct can be excited independently of consciousness and of the brain; in fact Dr. Laycock goes further and says, "there are phenomena, however, in favor of the doctrine that the medulla oblongata is the common sensory of all conscious states, whether they refer to corporeal processes or the purely encephalic changes associated with ideas.

Mind manifests itself through its threefold states of intellect, emotion and will, and it is striking to observe how the consensus of opinion among physiologists is that the sensory ganglia, pons and medulla are the seats of the emotions. Whether Brown-Séquard, Noble of Manchester, Prof. Cleland of Glasgow and other great physiologists are correct in stating that the medulla is necessary to the manifestation of mind, I leave the profession to decide.

RECENT PROGRESS IN MENTAL PHYSIOLOGY.

Presented in the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY E. P. HURD, M.D.

PROFESSOR OF PATHOLOGY AND DERMATOLOGY, COLLEGE PHYSICIANS AND SURGEONS, BOSTON, MASS.
NEWBURYPORT, MASS.

It is unquestionably true that this century has witnessed greater advances in the knowledge of mental physiology than all the ages that have gone before. The nervous system and especially the cerebrum were, prior to this century, almost a *terra incognita*. We may not know more respecting the properties of mind than our forefathers did, but we understand as they could not the conditions of mental action.

PHRENOLOGY.

The movement inaugurated by Gall and Spurzheim early in this century undoubtedly added a powerful stimulus to the study of mind. The doctrine of localizations in the brain then first was given formal statement. Although the body of teaching comprised under the name of phrenology was erroneous, there was some truth which gave the system the success which it for a time attained. Attention was powerfully directed to the physical correlatives of mind and the so-called mental faculties were analyzed and defined with considerable precision. We now know that there is no such relation between faculty and organ as the phrenologists affirmed, but the modern investigator has been aided in the study of the true doctrine of cerebral localization by the hypotheses and mistakes of his predecessors.

THE EARLY PHYSIOLOGISTS AND THEIR SUCCESSORS.

The work of Bichat, in the first part of the century, was highly advantageous to physiologic inquiry. He first defined the elementary tissues (his classification with some modifications being still in current use), and called attention to the vital properties of the tissues. This conception became fruitful in its application to the nervous system. He was the first to predicate sensibility of all the organs, which, he says, "forms their vital character." In 1811 Sir Charles Bell first demonstrated that there are nerves of sensation and nerves of motion, and he roughly sketched motor and sensory localization in the spinal cord. The way was now open for other researches localizing function and

specifying properties in different parts of the nervous system.

The science of biology has sprung into being during this century, and as a result of perfected microscopes, the cellular structure of all organic and vegetable tissues has been revealed. The field of vision has been extended to the domain of the infinitely little. The truly functioning (parenchymatous) elements are groups of cells which, the more we study their marvelous properties, seem the more endowed with the attributes of intelligence. We may fairly compare the behavior of the leucocytes and other living cells of a part invaded by hostile bacteria to the actions of a colony of ants when their citadel is attacked by an enemy; and the true tissue builders of the organism may be likened to the honeycomb fabricators of the hive.

Since the discovery of protoplasm, it has been shown that even the cell is not the fundamental unit, but that the essentially living substance is independent of structure and endowed with the properties of nutrition, growth, reproduction and movements, apparently spontaneous. I shall not discuss the question whether there be any real spontaneity in the movements of the matter of life. Some (as Claude Bernard) insist that the seemingly independent movements of protoplasm are caused by the impact of forces in the environment.¹ On the other hand, Lionel S. Beale in his numerous writings claims the separate existence of a transcendental power, "vitality," as the agency upon which the composition, character, minute structure and action of all tissues and organs in every living organism directly depend. It is not derivable from or correlated with the natural forces, light, heat, electricity, etc. This is dualism pure and simple, a conception from which the scientific world has been steadily moving. It has hampered science in the past, and has been unfruitful of progress. All admit the mystery of life, and it is as great as the mystery of mind.

MIND, ONE ASPECT OF LIFE.

Prior to about the middle of the last century, the most vague ideas of cerebral physiology were entertained. Although the brain was held to be the organ of mind, the latter was not regarded as the function of that organ,² consequently the study of mind was not connected with the study of the nervous system.

Hartley, in 1748, made the first attempt to explain psychologic phenomena on physiologic principles. Locke's treatment of the subject is of the vaguest kind, although he had attained to a singularly correct biologic conception of man, whose identity (like that of the plant and animal) consists in "a participation of the same continued life by constantly fleeting particles of matter in succession vitally united to the same organized body."³ Hartley was the first to speak of motions in the substance of the brain (called also by him "oscillations" and "vibrations") as concomitants of thought. Erasmus Darwin's theory is substantially the same as Hartley's, though he had a

dim idea of psychology as based on the laws of life. On this basis Cabanis early in this century instituted his psychology. He first distinctly connected the operations of intelligence and volition with the origin of all vital movements. Life and mind were treated as correlative. The consequences were immediate. If mind was to be studied as one aspect of life, it must be studied through that inductive and experimental method which has reached the certain truths of positive science.⁴

No author has carried forward this conception as far and established it by such a wealth of fact as Herbert Spencer, whose "System of Psychology" has been an epoch-making book, profoundly affecting all subsequent psychologic writings.⁵ In the light of the Spencerian philosophy, human psychology is only a part of animal psychology, both dealing with orders of phenomena to be studied under the head of general biology. Mind in the last analysis is resolvable into units of feeling, whose objective counterpart is a nervous shock or series of shocks occurring in the living protoplasm of a nerve center. This conception assimilates human to animal intelligence, and whether best explicable by the monist or dualistic hypothesis, is quite inconsistent with the assumption of any radical difference between the human and the brute mind. If the one needs an immaterial agency to account for its existence, so equally does the other.

In Spencer's system the inorganic comes first, then the lowest forms of vegetable and animal life, then forms of life that have a relatively developed mentality, and finally those that possess it in a high degree, like man.

If the chapter of inorganic evolution could be written, it would trace the development of compounds of matter of the simplest and most stable forms up to those highly complex and unstable compounds containing nitrogen, sulphur and phosphorus constituting the protoplasmic group. The gaps in this study can only partly be filled by a process of reasoning from the law of continuity. There is in the universe a constant redistribution of matter and motion, and these redistributions constitute the changes which we see; nothing new is introduced except what results from the redistributions. There is nothing in the evolved universe which did not exist potentially in the original nebula. The elements and forces which compose an organism existed previously as parts of other compounds. Everything has come into being through one method of evolution from lower forms. How is it with mind—with consciousness? When these first appeared was any new element added?

The consistent evolutionist denies that there has been any supernaturally interjected element. The hypothesis that there is any such element introduces confusion into his system. He may rightly rest in the agnostic position that we can know nothing of the ultimate nature of either mind or matter. He may adopt Spencer's thesis, that the unknowable manifests itself to us subjectively as consciousness and objectively as matter. Doubtless, as Boscovich, Faraday and Jevons believed, matter in the last analysis is simply force, *i. e.*, something immaterial, spiritual. Granting this, monism is the more logical doctrine. Everything has a transcendental side. Mind and matter have a common substratum. In its application to nerve centers, what is nervous shock on one side is

¹ Claude Bernard, *Lçons sur les phnomènes de la Vie*, states: The movements are spontaneous only in appearance. There are always exterior agents foreign to the living organism which provoke active manifestations in living protoplasm. In the higher animals these stimuli generally act through what Bernard calls "the interior environment," *i. e.*, the circulating blood.

De Lannessan, in his remarkable work (little known in this country): "Le Transformisme," defines life as "the sum of movements manifested by matter in that state of chemie composition and molecular aggregation which is the most complex of which we have any knowledge."

² The proposition that mind is a function of the brain must be taken with great limitations. See G. H. Lewes, *Biographical History of Philosophy*, Am. Ed., p. 608.

³ Essay on the Understanding. New York, 1825, p. 220.

⁴ G. H. Lewes: *Biographical History of Philosophy*, . 604.

⁵ Notably Maudsley, Taine, Ribot, Fiske.

feeling on the other. Consciousness is the correlative of the collective life of millions of cortical cells, each having an individuality and mode of feeling of its own. The proposition is incomprehensible, but it is not inherently absurd, as it is in accordance with all biologic fact. In all our mental life, the physical is so inextricably interwoven with the mental that by no analysis can we separate them. The application of this truth to the emotions is familiar to all. "The expression is not merely an external sign of the emotion, it forms an integral part of it. Even in a normal state where an expression is artificially produced, it gives rise to the corresponding emotion."⁶ Bain (who was I believe the first to publish a text-book on the mind with an introductory chapter on the brain and nervous system), has shown this with a wealth of detail in his "Emotions and Will." Take, for instance, his description of the physical accompaniments of terror, and conceive, if you can, of this passion existing without those physical expressions.⁷

It is impossible to present here even a summary of that important part of Mr. Spencer's work in which he traces the correspondence of life and mind throughout the animal kingdom. He affirms that if evolution be true, mind can only be understood by observing how mind is evolved. If creatures of the most elevated kinds have reached those highly integrated and extremely heterogeneous organizations they possess through modifications upon modifications accumulated through an immeasurable past—if the developed nervous systems of such creatures have gained their complex structures and functions little by little: then necessarily the involved forms of consciousness which are the correlatives of those complex structures and functions must have arisen by degrees, as it is impos-

sible to comprehend mental (as well as bodily) organization, without tracing its stages.⁸ No one at the present day has done this work so well as Mr. Spencer, and to his "Principles of Psychology" I must refer the reader for further details. He shows that the most general definition which can be given of life—the maintenance of inner actions corresponding with outer actions—also applies to mind, that the degree of both varies as the degree of the correspondence, and that we pass from the physical to the psychical the moment we rise above the correspondences that are few, simple and immediate. "Regarded under every variety of aspect, intelligence is found to consist in the establishment of correspondences between relations in the organism and relations in the environment, and the entire development of intelligence may be formulated as the progress of such correspondences in space, in time, in speciality, in generality and complexity."⁹

Lastly, he shows that the classifications current in our philosophies of the mind can not be true. "Instinct, reason, perception, conception, memory, imagination, will, etc., must be either conventional groupings of correspondences, or divisions among the operations which are instrumental in effecting the correspondences."

THE NEW PHRENOLOGY.

There is no doubt that the doctrine of localization of functions in the cortex cerebri, as based on the discoveries of Fritsch and Hitzig, and especially David Ferrier, has forwarded the progress of mental physiology. The former teaching, sanctioned by the authority of Flourens, was that the functions of all parts of the cortex were essentially the same. The gray matter was inexcitable by ordinary irritants. Mind was regarded as a principle residing in all parts alike, and the destruction of limited areas of gray matter might not seriously impair the mental powers; experiments on rabbits and birds on which ablation of portions of the cerebrum had been performed, were alleged in support of Flourens' doctrine, and the celebrated crow-bar case was made to do yeoman service. "A limited part of the cerebral lobes," says Flourens, "suffices for the exercise of all their functions."

It need hardly be said that such views of cerebral psychology have not at the present day a single scientific advocate, and are virtually abandoned, so that they do not merit formal refutation. I may include in this reprobation the traditional belief that the brain is a mere machine played upon by "the mind."¹⁰

It was a surprise to the world when the doctrine of motor centers in the cortex cerebri was first enunciated—that a considerable area in the parietal lobes which had been assigned by the early phrenologists to certain faculties of the mind, was a part of the motor mechanism of the body. Broca had found the center of articulate speech in the posterior part of

⁶ Binet and Féré: *Animal Magnetism*, p. 54.

⁷ I can not refrain from citing (though in a note) the illustration given by Prince Kropotkin in the *Nineteenth Century* for July, 1897. The intimate correlation of the psychical and the physical is shown in conformity with the recent discoveries of Ramon y Cajal.

"Suppose that the skin of the right hand is irritated by a burn. The end ramifications of some nerve fibers in the skin at once transmit the irritation inward, to a ganglion cell located near the spinal cord. From it a nerve impulse is sent along another nerve fiber which enters the spinal cord and there envelops with its end branches the dendrons of some neuron. The central nerve system has thus been rendered aware of the irritation of the skin, and in some way or another it will respond to it. The nerve current, after having reached the cell of that spinal cord neuron, immediately issues from it along a nerve fiber; and if that fiber runs toward a striated muscle of, let us say, the other hand, our left hand may touch or scratch the burnt part without consciousness of that action being aroused; it is a simple reflex action. But the nerve fiber of that same cell may divide into two main branches, and while one of them runs to the muscle of the left hand the other branch runs up the spinal cord and reaches one of the big pyramidal cells of the gray cortex of the brain. The ramifications of this branch envelop the dendrons of the brain cell and transmit the impulse to it. Then we become conscious of the sensation in the right hand, and we examine the burn. However, the pyramidal cell in the gray cortex is connected, through its dendrons and fibers, with many other cells of the brain, and all these cells are also started into activity. But the big pyramidal cells, in some way unknown, are the recipients and keepers of formerly received impressions, and as they are stimulated associations of previously impressed images—that is thoughts—are generated. A familiar association between a burn and oil may thus be awakened, and we put some oil on the burn. At the same time the nerve impulse was also imparted to that chain of ganglia (the so-called vaso-motor system), which is connected with the heart, the intestines and all other inner organs, as also with the blood vessels, the glands and the roots of the hair. And if the burn was severe, and very painful, the activity of the heart may resent it, as also the blood vessels; we may turn pale, shed tears, and so on.

Now, whatever hypothesis we may adopt to explain how an undoubtedly physical nerve impulse can be transformed into complicated psychic processes, each of which also ends in physical facts, it can now be affirmed that the paths which the nerve impulse follows, and the activity which it starts in a number of cells of the brain, spinal cord and ganglia, are hypotheses no more. The electric effects of the nerve impulse as it is transmitted along such and such nerves, have been measured; its transmission from this or that cell of the cord to these or those cells of the brain has been tracked step by step; nay, the activity of the stimulated nerve cells in the brain and elsewhere has actually been determined, and the effects of fatigue in nerve cells have been studied in detail. And when the anatomist maintains that an irritation of the skin will be transmitted in this way and not in another, to such cells in such cases, and start into activity such cells of the brain, this is speculation no longer. It is a fact of natural science, firmly established, and verified in different ways by a mass of materially controlled observations."

⁸ *Principles of Psychology*, Vol. 1, p. 292.

⁹ *Loc. cit.*, p. 385.

¹⁰ There is a sense in which these views are correct. Munk, in answer to the question, "Where is the seat of intelligence?" replies (and in this answer we see how far the new psychology has diverged from the old): "Intelligence has its seat everywhere in the cerebral cortex and nowhere in particular. It is, in fact, the sum or resultant of all the images or representations derived from the exercise of the senses. Every lesion of the cortex alters the intelligence more or less profoundly, in the ratio of the extent of the lesion. This it always does by the loss of those groups of images or representations, simple or complex, whose seat is the cortical territory injured. The intellectual trouble will be definite: 1. If the perceptive elements are destroyed; 2. If there remains no more substance which can become the seat of the functions lost. Blindness, deafness, psychical paralysis, complete or incomplete, of one part of the body entail greater or less contraction of the field of intelligence." Soury, *Fonctions du Cerveau*, page 117.

the third left frontal convolution. Ferrier found this center to be a part of the motor zone, which is formed by the juxtaposition of several centers, each presiding over the motion of a member, or of a muscular group on the opposite side of the body.

The topography of the motor or cortical centers in man is well demonstrated by the anatomo-clinical study of motor paralysis of cortical origin.¹¹ These paralyzes are extensive or circumscribed according as the lesions of the cortex on which they depend are considerable or inconsiderable in extent, and they affect this or that part of the body according to the precise point in the motor zone in which the lesions are situated.

These are the motor centers (*libero-motor*) of actions properly classed as voluntary and conscious; and even *ideo-motor* actions, originating in the cortex through awakened sensory images, find here their mechanism of reflection.

Here is the highest plane of transit of the sensory into the motor. Here are the centers where impressions not disposed of in the lower ganglia are finally reflected. If life and mind are the adaptation of inner relations to outward changes, here is the workshop where the finer, more delicate adjustments are made which bring the individual into most complete harmony with his environment. For these ganglia are in the closest connection with other ganglia (those of visual and auditory perception, etc.) in which are registered the experiences of a life time and during the psychic life of the individual they are responsive only to mandates from these higher centers. The infinitely numerous and varied neural communications between ganglia make possible the most complete functional solidarity.

The cells of the motor area (Rolandic region) register motor memories; they are *libero-motor* (Herbert Spencer).

The optic lobes in the lower vertebrates and their intra-cerebral expansions have a functional importance commensurate with their preponderant size, and although in man the corpora quadrigemina are relatively small, the cerebral expansions of the visual nerve apparatus occupy the occipital lobes and a part of the parietal (angular gyrus), in other words these parts of the hemispheres are appropriated to sight memories. Their destruction involves the loss of a wide territory of mind, all knowledge acquired by the visual sense. For it is now known that memory is a material record, "we may in fact assimilate the fixation of memories to an iconographic act, if the complexity of structure of the encephalon did not interpose an obstacle to such a schematization."¹² "To say that the cortex cerebri is a sensitive photographing plate on which are fixed the images of the external world is no longer one of those metaphorical formulæ which are employed to express empirically what can not be scientifically demonstrated."

There is a sense in which the term images as applied to the cortical memories is correct, but it should not be forgotten that we have to do here with vital laws, not physical.

If impressions may be "graven" on the cells of the visual centers, they may be weakened by fatigue or anemia or obliterated by disease, and instances are on record where whole groups of visual memories have been blotted out by softening while

the memories of other senses are left intact. The condition of the subject is truly deplorable, for he can no longer recognize objects, and all that he has learned by sight has perished. The distinction of partial memories, so much insisted upon by Ribot has been established beyond dispute. Charcot has devoted to this subject an interesting lecture in the third volume of his *Lectures on the Diseases of the Nervous System* (Leçon xiii). He gives the particulars of a case of loss of the mental vision of objects, forms and colors, coming on suddenly in a subject noted for great intellectual activity, but especially for the strength of his visual memory. After an attack, which seemed to be of the nature of a limited embolism, he lost his visual memory of forms and colors, and was obliged to have recourse to other forms of memory (the auditory, tactual, etc.) which were unimpaired. The "interior vision had completely disappeared." Charcot concludes his observations of this case by saying that, "It can not now be denied that the possible and actual suppression in numerous instances of an entire group of memories, of a whole category of commemorative images without the participation of other groups or categories is a capital fact in pathology as well as in cerebral physiology. It leads necessarily to the admission that these diverse groups of memories have their seat in certain determinate regions of the encephalon, and adds another proof to those already existing that the hemispheres of the cerebrum consist of a certain number of differentiated organs of which each possesses its proper function while remaining in the most intimate connection with the others."

The visual word center whose suppression gives rise to word blindness is in the angular gyrus. Lesion of this center is generally accompanied by hemiopia by involvement of the common visual center situated in its vicinity. Dejerine, who locates word blindness in the angular gyrus, thinks that lesion of this center always connects with it agraphia, writing being but the copy of visual word images evoked mentally.¹³ (See in opposition to this exclusive view Bastian in *London Lancet*, April 10, 1897, page 1012.)

The auditory word center whose destruction causes psychical word deafness is seated in the middle part of the first left temporal convolution.

Ferrier, Wernicke and Munk agree in localizing the center of audition in the temporal lobe, particularly in its upper portion; the first and second temporal gyri. This is the seat of sound perception, destruction of which entails loss of the memory, and consequently of the comprehension of words. There are now quite a number of cases on record in which the loss of word memories was consequent on softening of this center. Many cases have been recorded in which the patient's speech has been so disordered that he could scarcely say more than three or four connective words, and could perhaps utter no nouns, yet when a book is placed before him, he is capable of reading aloud correctly and with ordinary facility.¹⁴

Regarding the centers of smell and taste, it seems demonstrated that these are located in the sabciculum cornu ammonis, and in the hippocampus. We, however, lack positive data in this regard. It is also in

¹¹ Vide Charcot: *Centres Moteurs Corticaux*, p. 193. Paris, 1875.

¹² Bressaud: *Traité de Médecine*, Charcot, etc., Paris, 1895, p. 6.

¹³ See "Illustrative Cases of Aphasia," by Byrom Bramwell, Case 1, p. 796, in *Lancet* for March 20, 1897. He reports a case of agraphia with almost complete word blindness due to a gumma in the region of the left angular gyrus. This writer does not, however, admit that all cases of word blindness are accompanied with agraphia.

¹⁴ Bastian, in *London Lancet*, April 10, 1897, gives notes of three such typical instances.

the hippocampus that Ferrier locates the centers of tactile sensibility, but we require more definite knowledge on this point. There is good reason to believe that in man the motor areas of the cortex contain also the centers of cutaneous sensation.¹⁵ The frontal lobes undoubtedly make part of the sensitive or sensori-motor sphere of the cortex cerebri. They are, according to Ferrier, inhibitory motor. Electric stimulation causes no motor manifestations; their removal produces no motor paralysis, but causes a form of mental degradation which may be reduced in ultimate analysis to loss of the faculty of attention (Ferrier, *Functions of the Brain*, page 288).

Removal of these lobes also produces a peculiar change of character; animals become morose, irritable and violent, and similar changes of importance have been noted in them after serious injuries of these lobes. Removal of the occipital lobes seems more directly to enfeeble the intelligence, because, as Soury shows, the posterior cerebra have more to do with sensibility, and in the event of their mutilation, "the impossibility of inhibiting the centripetal irritations and of determining muscular movements co-ordinated in view of a useful end will give to the animal the aspect of a creature becoming demented."¹⁶ The anterior cerebra have a more strict anatomic relation with the motor apparatus; the posterior with the organs of sense. As long as these two cerebral regions are intact, the centrifugal currents of the muscular innervation may undergo an arrest, as well as the centripetal currents coming from the organs of sense. The cerebral reflexes enter in play, and the final reaction positive or negative, always results from the conflict of the psychic forces. But in the animal whose front brain has been removed, there is no longer anything to oppose the liberated currents of motor energy.¹⁷

"Man," says Ferrier, "is not merely a passive or receptive organism capable of registering impressions in the form of sensory ideas or feelings, but also an active or executive organism, possessing the power of varied and complex forms of motor activity. These motor activities called into play by definite feelings or sensations, actual or revived, constitute volitional movements, and the organic cohesion formed between the sensory and motor centers persistently enduring in these centers is the physical basis of our volitional acquisitions in all their manifold range and complexity."¹⁸

In accordance with these views, we can only regard intelligence as the resultant of all the images or representations derived from the perception of the senses. Every lesion of the cortex alters the intelligence, the more profoundly the greater the extent of the lesion; this it effects by the loss of these groups of images or representations, simple or complex, which have for their substratum the cortical territory diseased or destroyed.¹⁹

The familiar truth, *Nihil est in intellectu quod non prius fuerat in sensu* (there is nothing in intellect which was not previously in sense), has received striking confirmation from recent discoveries in mental physiology. What clear notion is it possible to form of mind apart from these stores of images that have

come in through the special senses? Reflection, imagination, ideation, discrimination are only possible as these images are awakened and brought into simultaneous intercommunication through that wonderful network of neural connections which exist throughout the cerebrum. But many of these organized acquisitions antedate the experience of the individual, and are a product of ancestral experience.

The human brain may be regarded "as an organized register of infinitely numerous experiences received during the evolution of life, or rather during the evolution of that series of organisms through which the human organism has been reached."²⁰

The physiologist of today is perhaps as far as his predecessors from a solution of the problem of consciousness. Consciousness is doubtless a primordial fact of ganglionic nerve activity under certain conditions. These conditions are now tolerably well known. It is not an activity that can long be sustained without interruption. It seems particularly to be associated with the disintegration of nerve element. Some writers, notably Herzen, regard it as the fervid glow of the sensorial centers. The illustration will answer our purpose, the qualification being made that we are regarding only the objective aspect of the subject. In this fervor all the elements of the cortex participate with a greater or less degree of intensity, by reason of that cohesion of neural groupings which constitute a solidarity of the brain functions.²¹

1. "Impressions are resuscitated or brought into consciousness in proportion to the amount of molecular change in the brain" (E. D. Cope). This statement is in conformity with Herzen's investigations (See "*Le Cerveau et l'Activité Cérébrale*," Part III.)

2. Events are resuscitated in proportion to the intensity with which they are impressed on our consciousness at the moment when they occur. This is a universal experience, and according to Cope is to be traced to the different degrees of molecular changes produced in the brain by the respective impressions. Cope, from whom I quote, gives appropriate illustrations. The facts of inherited memory are; that upon the appropriate stimulus being presented, as the cry of a hawk, a part of the impression made on previous generations of chickens, *fear*, is resuscitated in consequence of inherited peculiarity. The phenomenon is precisely that which occurs in the life of every single animal. Reminiscence is the bringing of mental states into consciousness.

3. Consciousness is dependent on a certain normal waking state of the cerebrum and integrity of the cerebral substance.

4. Consciousness is not coextensive with mind. The contrary was taught as a psychologic dictum by Sir William Hamilton, but it is not correct, nor is it altogether true to speak of mental phenomena gener-

²⁰ Herbert Spencer, loc. cit., p. 471. "Les perfectionnements ainsi obtenus dans une suite de générations finissent par devenir héréditaires et par faire partie des qualités de la race. Que de sentiments naturels aujourd'hui chez l'homme civilisé ne sont que des résultats d'une éducation continue de générations en générations pendant de longs siècles." Vulpian, *Physiologie Comp. du Système Nerveux*. The French physiologist has here brought out the same truth as is advanced above.

²¹ The following passage is from Herzen, "*Le Cerveau et l'Activité Cérébrale*," Paris, 1887:

"We are conscious in the waking state, unconscious when we sleep soundly; this is a first rough indication of the bond which unites consciousness to the disorganization of the active elements. I shall show further on that this intermittence subsists in each central act taken separately. The brain may, in fact, be compared to a room furnished with an immense number of gas-beaks, but lighted only by a number relatively small and relatively constant of illuminated beaks, which are not always the same; on the contrary they change at each instant; as fast as one is extinguished others are lighted up; all are never illuminated at the same time; at times all are extinguished."

¹⁵ See a paper by Dr. Charles L. Dana, in the *Journal of Nervous and Mental Diseases*, October, 1888, in which this subject is discussed from recent data.

¹⁹ Munk (cited by Soury).

ally as "states of consciousness." Mental power, as Maudsley well says, is organized before consciousness appears, and it is subsequently regularly modified as a natural process without the intervention of consciousness.²² Maudsley elaborated this fact with considerable completeness many years before the valuable contributions of F. W. H. Myers and Dr. Osgood Mason on the "Subliminal Consciousness" were published. Dr. Carpenter forcibly states the same truth in her "Principles of Mental Physiology," published in 1874. The subject has also been well treated by Dr. Laycock and by Dr. Oliver Wendell Holmes.

5. The process of association of ideas goes on in the brain independent of consciousness and the assimilation or blending of similar or different ideas is in no way under the cognizance or control of consciousness.²³

If consciousness is the highest form of cerebral activity, embodying primarily present impressions of sense, and secondarily the residua of past impressions (the results of individual and even racial experiences) with the feelings and emotions belonging to those experiences, it follows that the character and personality of the individual can not find expression without consciousness; in other words, the individual when under the domination of subconscious or unconscious states is an automaton rather than a rational man. This truth has been recognized in all ages; a man is only responsible for what he does consciously.

Doubtless trains of thought can go on without consciousness; we have evidence of this in our dreams, and in hypnotism. It is possible for subconscious states or groups of ideas to become "dislocated" and form a second personality. We find remarkable instances of this kind recorded in "Maladies de la Personnalité" by Ribot, and in Janet's "Automatisme Psychologique," and later works which deserve careful study. Hypnotism artificially arouses in the subject a second personality by paralyzing or inhibiting in some mysterious manner the upper consciousness.

I am aware that extraordinary claims have been made for hypnotism, but really nothing has ever been elicited from hypnotized subjects that was not before in their cerebrum as parts of their stored-up acquisitions obtained through the channels of the senses. Again we say: *Nihil in intellectu quod non prius fuerat in sensu*. The most that we can concede is that in some phenomenal cases there may have been a preternatural exaltation of certain senses so that the subject became in some way cognizant of influences at a distance.

As for "mind reading," I have no explanation to offer; I await sure proof that the fact exists. The stores of "memory images" in the cortex cerebri are not legible characters nor even hieroglyphics to be read by experts, but simply cell modifications, with their subjective counterparts.

We should be slow to adopt the conclusions of Myers, who has written profoundly of the "Subliminal Consciousness," in the Proceedings of the Society for Psychical Research. A vast amount of assertion is made on insufficient authority. Myers' conclusions may be in harmony with the old psychology; they can not be reconciled with the new. If the views of some of these men of the Psychical Research Society are true, we must give up doctrines which are the necessary resultant of the inductive study of mind of the past hundred years. If Mr. Myers is right, we

have learned nothing from the method of concomitant variations or the clinico-pathologic method based on the modern doctrine of cerebral localizations. This is no reason why we should reject proved facts, but it is important that we should weigh assertions and demand the most complete proof.

Dr. R. Osgood Mason has lately published a book entitled, "Telepathy and the Subliminal Self," which contains much that is simply as incredible as the prodigies which Suetonius describes attending the death of Julius Caesar, and is not better supported. The order of phenomena of which he writes is quite familiar to us through the claims of spiritualists, who base their beliefs on just such "facts." Modern spiritualism has been very thoroughly investigated and found wanting. I need only refer to the labors of the Seybert Commission and to the English Society for Psychical Research, which has done good work in exposing frauds posing as mediums and clairvoyants. The mediums of this country are almost without exception shallow impostors and charlatans banded together to help one another and to deceive the public. Prof. R. Hodgson virtually affirms this as the result of his labors in the United States in behalf of the Society for Psychical Research.²⁴

I am certain that the psychology of the future will not accord as much importance to the "subliminal consciousness" as does Dr. Mason. To him it is an unknown quantity of monstrous proportions, capable of all knowledge, past, present and future. Rather would we take the view of Janet, that it is the weaker self. "How far this splitting up of the mind into separate consciousnesses may exist in each one of us is a problem. M. Janet holds that it is only possible where there is abnormal weakness and consequently a defect of unifying or co-ordinating power. A hysteric woman abandons part of her consciousness because she is too weak nervously to hold it together. The abandoned part meanwhile may solidify into a secondary or subconscious self. In a perfectly sound subject, on the other hand, what is dropped out of mind at one moment keeps coming back at the next. The whole fund of experience and knowledge remains integrated and no split off portions of it can get organized stably enough to form subordinate selves."

This view of the pathogeny of the "second personality" I have given in the exact words of Professor James.²⁵ It is the view becoming more and more current among physiologists. The individual who is subject to these changing phases of personality, or who can assume them at will for purposes of gain, professing to be under spirit control is, like the hysteric or insane person (there are some forms of insanity in which the mental malady is a simple change of personality), a person of weak and depraved cerebral tone and stamina, a neurasthenic or a degenerate. It is folly to attribute to such weak-minded, depraved or degenerate subjects superior knowledge and insight and consult them on matters of the utmost moment, as is done by many. Science has in the past throttled superstition and will continue its beneficent mission. Spiritualism is based on old and obsolete views and must perish as men learn the new science of mind.

Let us defeat the Antivivisection Bill!

²² Maudsley, *Phys. and Path. of Mind*, Am. ed., page 15.
²³ Maudsley, *loc. cit.*

²⁴ See "Vampires of Onset," by John Curtis of Boston, for further proof. Mr. Curtis writes: "Nothing has come from spiritual or psychical societies of the least value to the world and all interest in them is fast dying out."

A COMPARISON OF THE ANATOMY AND THE FUNCTIONS OF THE CEREBRUM AND THE CEREBELLUM.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM FULLER, M.D.

GRAND RAPIDS, MICH.

In order to understand the anatomy and the connections of the cerebrum and the cerebellum, it will be necessary to present a cursory view of the general structure of the central nervous system. For the purpose of description it will be advantageous to divide the cerebro-spinal axis into three portions, which may be compared with each other by similarity of parts, though differing in their arrangement. The three divisions of the axis which I shall make are, the spinal cord, the cerebellum and the cerebrum. Each of these parts is divided into lateral halves by a median fissure. The lateral halves are united in the median line by a commissure; each portion encloses a cavity or ventricle which is continuous with that of the others, and each is composed of gray matter, of motor and sensory function, with commissures of white matter extending between the gray masses, or the nerve centers. The gray matter of the spinal cord is invested by the white columns of the cord, while in the cerebellum and cerebrum the gray matter or ganglia are everted, and the white substance enclosed. The crescent-shaped gray columns of the spinal cord are its inverted hemispheric ganglia, and the reticulated column by which these are immediately invested, corresponds to the corona radiata of the cerebellum and the cerebrum. The longitudinal white columns of the spinal cord are seven in number, are continuous with certain tracts of the cerebellum and the cerebrum, and may therefore be traced upward into these parts, and associated into general systems, by which method of study an understanding of the whole structure will be reduced to the greatest simplicity. Disregarding the direction in which the nerve impulses are propagated, we will begin in each instance with a column of the spinal cord and proceed upward, in order to avoid confusion in the anatomic relations. We will make use of the singular number in most cases, since it will be understood that each half of the axis is like the other.

1. The motor tract: The crossed pyramidal tract unites with the direct pyramidal tract of the opposite side of the cord to form the opposite pyramid of the medulla oblongata. The anterior pyramid of the medulla passes into the pons Varolii, is there connected with one side of the ganglion of the pons, which is the external basal ganglion of the lobe of the cerebellum opposite to that half of the pons. The pyramid is continued through the crura of the crus cerebri and the middle portion of the internal capsule and lenticular body, to the motor area of the hemisphere. The impulses propagated along this tract are downward, and are derived from the hemisphere of the cerebrum, and the opposite hemisphere of the cerebellum.

2. The ocular reflex tract begins below in the fundamental root zone of the spinal cord and, becoming compressed at the upper part of the medulla oblongata between the anterior pyramid, the olive and raphe, escapes in the pons Varolii to form a flat band in front of the fillet and, pursuing an upward and outward direction to the corpora quadrigemina, is continued

through the brachia and the geniculate bodies to its connection with the optic tract.

3. The fillet tract or the sensory tract of Gower: This tract commences below in the anterior root zone of the spinal cord, passes upward to the pons Varolii, where it lies behind the olivary fasciculus, and forms the middle layer of the fillet with which it is continued upward internal to the crura, which it crosses in an oblique direction to reach the frontal convolutions of the cerebrum. This tract is augmented in size as it passes upward by accessions from all the sensory ganglia and, with the large mass of fibers derived from the thalamus, this system forms the anterior portion of the internal capsule of the cerebrum. The probable function of this tract is to form a direct communication between all the sensory ganglia with the seat of consciousness and intellect in the anterior lobes of the brain.

4. The cerebello-spinal tract: The direct cerebellar tract of the spinal cord connects the cerebellum with the vesicular column of Clarke. The function is supposed to be trophic.

5. The organic sensory tract: Beginning in the posterior root zone of the spinal cord, it is interrupted in the medulla oblongata by the restiform ganglion, is continued upward to the cerebellum by the restiform body entering the corpus dentatum, or internal basal ganglion of the cerebellum, and to the cerebrum through the processus, red nucleus and thalamus to the occipital and temporal lobes of the hemisphere, which is the seat of the memories. It is probable that the impressions received by this tract are co-ordinated by the cerebellum, and organized into memories in the cerebrum. The region of the memories in the cerebrum is associated with the fillet system and the frontal lobes by means of the great longitudinal commissures, the import of which is, that the present impressions received through the fillet system of fibers just mentioned are thus associated in the intellect with the organized impressions of the past which, as I have before stated, are located in the posterior and temporal lobes of the brain.

6. The respiratory reflex tract is formed by the posterior median columns of the spinal cord which, terminating above in the clavate nuclei, are through these bodies connected with the centers of the sensory respiratory nerves.

If we add the speech tract to those above described, it will be observed that we have included almost the entire cerebro-spinal axis into four short and into three general groups or tracts. For our present purpose we may omit the former groups, and regard only the latter, viz., the motor tract, the fillet or direct sensory tract and the organic sensory tract. The cerebrum is connected with all three of the latter tracts but the cerebellum is not associated with the fillet, being devoid of consciousness and intellect, but with the other two tracts only, viz., the motor and the organic tracts. The parts which enter into the structure of the cerebrum, or into the cerebellum, are the internal capsule and basal ganglia, the transverse commissures, the corona radiata and the hemispheric ganglia, a comparison of which several parts will now engage our attention.

The internal capsule of the cerebrum is composed of three distinct parts: an anterior portion which is distributed along with the longitudinal commissures to the frontal lobes of the hemisphere, and is receptive in function; a middle portion, derived from the

parietal or motor area, and is motor in function; and a posterior and inferior portion, derived from the internal basal ganglia and distributed to the occipital and temporal regions of the hemisphere, the function of which is sensorial and organic, and which therefore contains the memories. The internal capsule of the cerebellum also contains three parts, viz., the restiform body, which connects it with the spinal centers; the processus, which connects it with the opposite cerebral hemisphere; and the deep layer of the transverse fibers of the pons Varolii, which connects it with the ganglion of the opposite side of the pons Varolii and the opposite motor tract of the cerebrum. The latter portion of the cerebellar internal capsule is its motor tract, which therefore decussates with its fellow in the middle line of the pons Varolii, in order to reach the motor tracts of the cerebrum previous to the decussation of the latter in the medulla oblongata, which supposition appears to be amply demonstrated in a hemimicrocephalic specimen in my possession, as well as from the consideration of the physiologic probability.

The restiform body and the processus both belong to the organic sensory tract and are continuations of the same. The internal basal ganglia of the cerebrum are sensory, and the external basal ganglion, or lenticular body, is motor in function, and each is connected respectively with the sensory and the motor tracts before described; their names indicate their relation to the internal capsule. So likewise the basal ganglia of the cerebellum are called internal and external, and are correspondingly sensory and motor in function. Its internal basal ganglion is the corpus dentatum, in which the restiform body terminates and the processus takes its origin. The external basal ganglion of the cerebellum, as before stated, is within the opposite half of the pons Varolii, being thus displaced to be associated with the opposite motor tract of the cerebrum, with which its function is allied. The corpus callosum of the cerebrum is a broad band of transverse fibers which unites its opposite hemispheres, and its analogue in the cerebellum is the superficial layer of the transverse fibers of the pons Varolii. The correspondence between the corona radiata and of the hemispheric ganglia of the cerebrum with the same structures of the cerebellum are sufficiently evident that they only require to be mentioned.

The size of the cerebellum relative to that of the cerebrum in different brains is worthy of note in reference to the effect upon the character of the individual. A large cerebellum is associated with a large development of the nutritive functions, and commonly with the existence of great force of character. Men thus endowed occupy the first place in the public estimation, while those of intellect occupy the subordinate position of advisers. The intense desires originating in a large cerebellum are not obstructed by the contracted foresight of a small cerebrum, and on the other hand a large cerebrum often magnifies the difficulties which lie in the path that leads to success. The man who is well balanced by a due proportion of these masses is happily constructed.

The above observation is supported by a comparison of several brains in my possession of persons with whom I was well acquainted in their lifetime, and I think that common observation will lead any one to the conclusion that a large abdomen is a stronger indication of greatness than a great head.

This leads to a consideration of the relative func-

tions of these portions of the brain. We have observed that the cerebrum is built upon those tracts of sensation one of which furnishes it with material for direct perception, and the other organizes within its cells not only the impressions of past experiences, but perhaps also the inherited tendencies of a former generation. These are associated by means of the longitudinal commissures of the brain and the conscious judgments, ever varying with each successive stimulus, are reflected upon the motor tract in obedience to the mandates of the will. The activities of the cerebrum are those which produce sudden and active change of the organs of motion, in order to accommodate the individual to his environment. The activities manifested as the result of cerebral disease are those of mental disturbance, chorea, athetosis, etc. The lateral masses of the cerebellum are connected wholly with the organic sensory tracts and with the motor tracts of the opposite cerebral hemispheres. Each hemisphere of the cerebellum is directly attached to the same side of the spinal cord and receives impressions from the same side of the body to which it belongs; its motor tract crosses over in the pons Varolii, but is returned to the same side of the cord at the decussation of the pyramids of the medulla, in which the arrangement of the cerebellum differs from that of the cerebrum. It is a mystery which surpasses my capability of solution, why the tracts leading to the cerebrum are crossed. My present impression is that it is the function of the cerebellum to co-ordinate the nutritive functions of the body, and as the mental states of feeling, indicated by desires and passions, depend largely upon conditions of the organic nutrition, it is therefore very probable that the immediate support of the feelings of the mind rests upon conditions within this organ. This is the opinion of Laycock, who thinks that the cerebellum is virtually a great sympathetic center, and thus sustains about the same relation to the sympathetic system as the cerebrum does to the cerebro-spinal system, which I am inclined to accept. The movements produced by the cerebellum, if this theory is true, correspond to changes of organic nutrition and must necessarily be slow, and are manifested externally by attitude and such expression as one can read upon the countenance of an individual in a state of rest. To sum up in a general comparison, I should say that the cerebrum is the brain which represents a knowledge of the world, while the cerebellum represents the physical condition of the man.

It is not to be expected that I should give a complete exposition of the anatomy of the brain in the short time allotted to the reading of a paper, but I have seized upon this opportunity to express what I believe to be the only proper and useful method of studying the central nervous system. The study of the anatomy of the central nervous system should be prior to the investigation of function, for without the aid of anatomy all attempts toward the determination of function, of localization and diagnosis are futile.

Oblique Incision in Sectio Cæsarea.—Fritsch finds that there are many advantages in favor of an oblique incision of the fundus, parallel with the vessels. He recently practiced it and found the entire operation only required twenty-nine minutes; the fetus was extracted with ease; the hemorrhage was very slight and stopped after the removal of the placental sinus, without compression of the cervix. The abdominal incision can be made higher up, thus avoiding danger of hernia later. The operation was remarkably clean. No blood entered the abdominal cavity.—*Cbl. f. Gyn.*, No. 20, 1897.

THE PHYSIOLOGY OF RIGHT- AND LEFT-HANDEDNESS.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY GEO. M. KELLOGG, A.M., M.D.

CHICAGO, ILL.

Much as this subject has been discussed, it does not seem to have been approached from the right point of view.

The young infant is in evidence, whose manifestations and peculiarities have been entirely overlooked. First, there is no asymmetry of body or function in early infancy. The child uses its two arms, legs and hands equally well. If there is any heredity of one-sidedness, it does not appear. The first day of life one thing is especially manifest. Beyond all other parts of the body, the hands show greatest development in function. Flexion and extension of fingers, hands and arms are wonderfully perfect and truly bilateral. The first day of infant life the grasping power of the hands is extraordinary. If permitted to clasp a pole with both hands it does so with firmness and will easily sustain its entire weight for a prolonged period. All other parts of the body show comparative weakness and uncertainty of function. This indicates that the hands are developed early, so that the child may become acquainted with its surroundings. The extraordinary clasping power of the hands has amused even the evolution philosophers, who have presumed to declare it a reminiscence of bestial prehensility of claw or tail. However, it is a distinctly human trait. The hands are alert and well developed to feel their way into the world. The sense of touch comes first. Our hands are the first teachers of the properties of things, of roughness and smoothness, of heat and cold, of distances. All these as results of sensation are recorded in the brain through what we call sensory nerves. These nerves or conductors pass up from both sides to the posterior columns of the cord and through the medulla oblongata to each brain.

In the medulla oblongata a peculiarity of organization appears. The nerves from the right side pass, in greatest bulk (about 90 per cent.) to the left cerebrum. From the left side of the body 90 per cent. pass to the right cerebrum, while a small portion (about 10 per cent.) pass straight or uncrossed to the cerebrum of their own side. Thus each half brain is functioned to control both sides of the body, but with great preponderance the left cerebrum controls the right side of the body and the right cerebrum the left. If both sides of the body were used exactly alike the two brains would receive equal or uniform records of sensation. The same is true of the motor or efferent nerves. These also cross in the medulla oblongata from the left to the right side of the body and from the right to the left side in a similar disproportion. If each side of the body, through the hands, was trained exactly alike, the same records or memories of sensation and movement would be printed on the cerebral cortex of each brain. The two brains would become as ambidextrous as are the two eyes, which have an exactly similar crossing of nerve fibers in the optic commissure, whereby the eyes either together or singly carry to the sensorium the same impressions. It needs but little argument to show that were the two eyes separated from each other for the first few years of life, the habit of one-eyedness would become

established, and they would never learn to act coincidentally.

"Custom alone can overcome nature," says Bacon. Have we not reason to suppose that nature, as evidenced in the anatomy of the body and the nervous system, may be defeated by a convention or custom established and persisted in from the infancy of the race? There is no animal, mammal at least, which is not perfectly ambidextrous. At least I can find no evidence of one-sidedness, save in man. This habit seems to have been established in early ages, probably before the historical period. The first occupation and duty among men was to fight and kill each other, for which purpose they desired one stronger hand to wield the club, spear and sword, while the left hand was relegated to carry a shield, and by custom, superstition and fancy it has persisted ever since. It is the exceptional parent, to this day, that neglects to train the child to right-handedness. Perhaps no mother or conventional nurse ever fails to place an object for the infant to clasp save in its right hand. That right-handedness is not natural, however, is evidenced by the oft-repeated left-handedness observed among us.

The left-handed habit is doubtless started in spite of the watchfulness of the parent during the critical period of babyhood, after the seventh month, perhaps on account of a burn, a strain or hurt of the right hand. The child at once brings the left hand into use, and in a few days, weeks or months the left hand habit becomes established with such force as to discourage the parent. All efforts weakly persisted in fail to correct it.

In the most primitive condition of man, before the custom of warring with each other existed, man as a hunter did not use the sword and shield. Perhaps then the two hands were brought equally into play. One or two authors have contended that early man was more ambidextrous than we; however, it seems impossible to confirm this. Among the early Hebrews the soldiers of the tribe of Benjamin were trained to left-handedness and the ancient Jewish script was from right to left. However, right-handedness has been in vogue through all the historic period. Left-handedness was in language equivalent to awkwardness—to the wrong as opposed to right (*droit*). The left was the weak, evil or sinister side. Men spoke of the "bar-sinister" "born on the left side of the blanket." It was the unlucky side, and the superstition of man became an early sponsor of qualities attributed to the left side. The ancient augurs observed as unfavorable the flight of birds to the left.

The importance of ambidexterity may be readily concurred in the increased capacity for labor obtained thereby, to the respite afforded to one hand by the use of the other, and the instant substitution of one hand for the other in case of injury to or loss of its fellow. I have known many cases of partial ambidexterity among mechanics and others, who could use either hand to saw and cut with, or draw a nail. Such were always proud of the accomplishment and realized its great advantage.

I have never seen but one case of complete ambidexterity. This was the late Alexander Mott, M.D., of New York, who used either hand in writing and the most delicate dissecting, in which his skill was marvelous. He told me he was always ambidextrous; that his father (the celebrated Valentine Mott) said, "My boy must succeed me in practice and I shall see

to it that he has two good hands instead of one, like his father." This case shows the practicability of effecting perfect ambidexterity by careful training.

Over a century ago Dr. Franklin wrote a short article for the French encyclopedia in which he personified the left hand as the neglected member and remonstrated against the absurdity of the conventional one-sided body.

Seventeen years ago Brown-Séquard came to this country and delivered his lecture on the "Dual Brain" in Washington, Philadelphia and Boston, in which he warmly urged the training of children to ambidexterity, in view of the reaction of one-sided body training in limiting the development of proper brain functions. Nevertheless his sensible views, presented in the zenith of his fame and influence, fell still-born before the medical world, contrasting sharply with the favor his theory of internal feeding has received from the same public.

The key to the whole question of one-sidedness of body is the establishment of habit. The nervous system converts the whole body into a unit, knitting together the most distant parts.

The nerves are conductors to and from the brain-pathways of the great currents of life. Habit is defined as the tendency of a given act to repeat itself in the realm of animal life. Habits are, from comparison, called ruts, like the channels which water wears in descending from a height. They become deeper and deeper as the current continues and soon become too deep for the possibility of another channel being formed. Certain nerves to and from a group of muscles control them, at first unequally, but after a while the muscles are compelled to act in unison. At last in the effort of adjusting to harmonious action a muscular movement, at first clumsy and slow, becomes almost automatic; each detail of the movement becomes as it were obliterated. We can not say each nerve conductor does not act separately though we do say the action is instantaneous. However, we recognize with very delicate instruments that the time element does enter. A certain moiety of duration occurs in all rapid conjoined movements, yet we know also they are not strictly automatic, for if one or more of the nerves of a group of muscles be cut between the group and the brain, the action is destroyed as surely as though a wire be cut in a complex system of telegraphy. Beginning with the first action habit becomes more confirmed with each successive act, also easier and more rapid. The effect of habit is especially seen in the successive and simultaneous action of voluntary muscles which are united, as in writing. In these muscular associations if an impulse is started it runs, perhaps, through a long list of words without fresh impulse. The adroitness of handling the pen in continued motion is a matter of education and habit. The musician affords a striking example of the development of the finger movement.

The many paired muscles and nerves of vocalization are so much under the control of the association habit, that were it not for this, no one could ever learn to speak. The power of habit is seen in the association of ideas. We speak of habits of drunkenness, swearing, lying and every modification of speech a thought; habits of industry, order, idleness, vanity, cheerfulness, melancholy; we are called bundles of habits. Habits, also, instead of increasing sensation often lessen it. We habitually come to disregard, after a while, our clothes as well as sounds, though at

first conscious of them every instant. Thus habitual motions become changed from volitional to so-called secondary automatic actions as in walking and speaking.

The action of the vocal muscles is preceded by sensation, idea and volition, but after a while it becomes purely sensational or ideagenous—easy and as it were automatic. Habit, first the offspring of volition, seems to become its successor. The force of habit thus compares with instinct, and education vies with intuition when habit becomes second nature.

Habits once acquired are not easily discontinued. They are grooves in which the mind is accustomed to move. The great importance of habit is perceived to be economy of time. Through rapidity of muscular action a complete unity of our complex animal organization is effected. To form ruts or habits in the nervous system becomes the potent cause of one-sided action of body and brain. This is seen in the great right and left side deftnesses which become permanent and assume an undue importance in our economy. It is sometimes the left side but nearly always the right. It might as well be both sides.

Besides Dr. Mott, it is said that Dr. Pancoast of Philadelphia, was nearly if not quite an ambidexter; also, Prof. Morse the inventor of the electric telegraph machine.

It is difficult to find in history many examples of ambidexterity. Homer's Iliad describes one of his warriors as throwing a spear with either hand, also some of David's men-at-arms could use both hands. Leonardo da Vinci and Michael Angelo are known to have been perfect ambidexters. Leonardo Da Vinci was not only a distinguished sculptor and painter but a great inventor, machinist, architect and engineer. It is said that after his seventy-sixth year, while working on an order of Francis the First, he was struck with right-sided hemiplegia; he however, continued his work with his left hand and right brain, which was doubtless, from training, equal to the other in functions. Michael Angelo was a man of great intellect and physical energy and lived to great age. It is remarkable that these two eminent men are placed by our Italian statistical and science-gossip Lombroso on account of this feature among his "molloids" or degenerates, who happen to share in the manual dexterity of pickpockets. The latter from neglected training or from obvious professional reasons furnish 1 or 2 per cent. more cases of left-handedness or perhaps partial ambidexterity than are found in the normal population.

We believe the crossed fibers to either brain is a real switching-off apparatus intended as in the case of the eyes for a temporary use. But human custom elects one side to permanent control. The result is then inevitable that nearly all our cerebration is thrown upon one cerebrum, whereby it becomes overtaxed, as it furnishes the nervous energy for both sides of the body through the crossed and direct tracts. It is a reasonable supposition that this leads to brain fatigue and failure, and becomes the most prominent cause of insanity and brain softening. The result of electing the right hand to special action reacts to establish the left brain to control. We find the most important function of speech and language as well as the faculty of discriminating sounds or the power of musical expression located around the left Sylvian fissure, which is clearly indicated by pathologic lesions.

The apparatus of nerve decussation becomes of no importance after the habit of one-sidedness has been established. The brain commissures, even the great corpus callosum, become for the same reason of little or no effect. I find twenty-five cases reported of absence and destruction of this important structure, by disease, with but little disturbance of general brain functions. So decidedly is this true that Dr. Bruce, who has made the largest collection of cases, declares his doubt of the usefulness of the corpus callosum in effecting co-ordination of brain action. The one-sided body-habit clearly makes this large anatomic structure as well as decussation of no effect, defeating thereby the clear purposes of nature as exhibited in all mammals, whereby we should possess two well paired brains perfectly responsive each to each.

The assumption, so generally in vogue, that one-sidedness is natural is only based on the evidence of majorities, leaving out of consideration choice, fashion or custom and the known effect of training, which, in the human race, is absurd. Statistics as respects mankind, for this and other reasons, are eminently misleading.

All arguments based on anatomy as forcing right-sidedness are very weak. The weight of organs on the two sides are not very unequal and the points of support are central from the spinal column. The very slight differences in length, size and direction of the two carotids in front and the vertebrae behind, as affording an unequal supply of blood to the brain, are of no effect. By their many peculiar curvatures while entering the cranium, by their abrupt change of direction to the horizontal at the base of the brain, the opposing currents neutralizing each other, and by the remarkable common reservoir-like circle of Willis the circulation in the two brains is almost, if not perfectly, equalized. There is no difference in the infant in the muscular and body tissues, contrasting sharply with the adult.

THE RELATION OF PHYSIOLOGIC PRINCIPLES TO ARTIFICIAL RESPIRATION.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD DAVIES McDANIEL, M.D.

CAMDEN, ALA.

As matter is known only by its properties, so life is known only through its functions and other manifestations. Its state or condition is judged from these. It often happens that by concussion and other forms of shock, by submersion in water or other fluid, by smothering and other modes of suffocation and strangulation, by extreme debility and exhaustion, by exposure to cold or heat, by starvation, by the influence of various narcotics and anesthetics, by sudden influence of grief, surprise, fear or other passion, and very notably, by the failure of a prompt occurrence of breathing of the fetus when it comes from the mother, a state of apparent death (call it obscured or depressed life if you choose) is presented. This state has been variously called drowning, asphyxia, syncope, apnea, etc. On proper examination it will be found that the functions of life which are in abeyance in this state of apparent death or depressed life are these: Innervation, respiration, circulation, calorification, sensation, reflex action, phonation, consciousness, voluntary motion, involuntary motion and muscular

irritability. It will also be found, after sufficiently numerous and careful observations, that by physiologic law these functions and vital manifestations are so related that whenever any one of them is restored all the others have a tendency to reappear, and whenever any one of them is depressed or impaired all the others show a corresponding depression or impairment. They are so connected that their inception is in a manner simultaneous, their course concurrent, their activity proportionate and their disappearance approximately coeval. This important physiologic law is of great value in the treatment of the depressed states of life. It suggests that the practice of resuscitation should include all known means and expedients which tend to develop all essential functions that may be undeveloped, to restore such as may be suspended and to counteract the bad effects that may result from the want of all those that may be either suspended or undeveloped. As a rule, the function which in any given case first became embarrassed or depressed or suspended and which led to the embarrassment, depression or suspension of the other prominent functions, should be made the prime or main object of remedial treatment. If, for example, by exposure to excessive cold the temperature of a patient has been so reduced as to depress notably or suspend sensibility, motion, etc., the first and most urgent indication is to restore the proper temperature by suitable expedients. If innervation is, from any cause, primarily impaired, the leading measure should be its restoration by electricity or other available appropriate nerve excitant. If the breathing has from any cause been arrested and its arrest has superinduced an embarrassment of the many functions dependent thereon, then artificial respiration is plainly the measure to which we must look as the direct means of restoring the patient.

There is another rule that should not be forgotten in the practice of the art of resuscitation. Though the vital functions are co-ordinate and have an intimate connection they do not all, when disturbed or suspended, involve in equal disturbances or dangers the immediate existence of life. Some are more rapidly influential than others and have therefore a leading importance in practice. The greatest of these, or among the greatest, is respiration. It is the herald of all higher life. It is the harbinger of calorification, of voluntary motion, of digestion, of secretion and of excretion. No human form can give forth any of the higher manifestations of a living soul until there is breathed into its nostrils the breath of life. Hence, among the measures for resuscitation, artificial respiration is entitled to prominence such as natural respiration possesses among the functions which it is the object of resuscitation to restore. Indeed, many of the other measures employed for resuscitation, such as exciting reflex action by spanking the newborn, slapping the pit of the stomach of the adult, squeezing, rolling, twisting, compressing, dilating the sphincter ani with the finger, exciting the rectum with injections or suppositories, using dashes of hot and cold water alternately, immersing in a cold or mustard bath, rubbing with rubefacients, tickling the fauces or nares, using volatile excitants, etc., and the usual preparative of clearing the lungs of gases, mucus, water, blood and other obstructions, though occasionally inaccurately mentioned as modes of artificial respiration, are at the very most merely preliminary and adjuvant thereto. Some of them are

useful, some worthless, and all that are harsh or rough or rapid may be harmful by augmenting an existing condition of collapse.

In addition to the intrinsic merit of artificial respiration there have been other causes of late to urge its importance upon the attention of our profession. In the course of the current half century the great battles, campaigns and wars that have occurred, the augmentation and multiplication of industries and pursuits perilous to life and health, the increase and concentration of population, the allurements, comfort and speed of voyage and travel, have multiplied the cases of accidents and injuries. In response to the demand thus increased, the humane and Christian sentiment of the period aroused itself to great activity in the formation and training of life-saving organizations and in the study and teaching of life-saving methods. During this same progressive half century it came to the knowledge of practical obstetricians (an appalling fact) that thousands upon thousands of speechless human lives were being annually lost at the hour of birth from the lack of a well-devised, prompt and appropriate management. It is not surprising that so great a demand for life-saving methods should tend to produce an over-supply, a result that seems to have happened in the matter of artificial respiration. Previous to 1856, *insufflation* in one way or another was the traditional mode of introducing air into the tubes and vesicles of the lungs of the so-called asphyxiated, especially if these were newborn babes. There are now at least twenty methods, more or less widely known. These differ so greatly and in so many respects that it is not supposable that they can all be equally applicable to all cases, or even to any one case. Some of them are based upon one principle, others on a very different and in some respects conflicting or contrary principle. Some of them may be more appropriate in some cases and less so in others. Some may be admissible in certain cases and inadmissible in others. Some are not safe in any case. Some are claimed to be best suited to the cases of infants, some to those of adults and some to be the best for patients of all ages and sizes. Some of the methods originated in accident, some came prematurely as an urgent need after older methods had been tried and had failed; some after too little observation, experiment and study; a few after profound and prolonged consideration.

There are too many methods. Doubtless the fittest will ultimately survive and the less fit will one by one pass out of use and there will result to the physicians of the world a safe, uniform and effective practice in artificial respiration. But this needed result ought not to be left to the slow work of unaided evolution. A firm reliance may be placed in the sure, safe and necessary guidance of science for the settlement of the facts of science. Wherever there is great variety, diversity or contrariety of method, precept or practice, an appeal to scientific principles, experiments and demonstrations is the direct pathway to truth, harmony and unanimity, and through these to wise methods and successful practice.

For brevity and clearness, it is best to say no more now of the collateral measures and aids in resuscitation and to force into close conspectus:

1. The condition to be remedied by artificial respiration and exactly in what this consists.

2. The lesson to be learned, mainly from physiology, but sanctioned also by anatomy, pathology and

clinical medicine, as to the proper mode of accomplishing artificial respiration.

3. The leading methods of artificial respiration now in use and how far they conform or fail to conform to physiologic principles.

The condition to be remedied by artificial respiration is apnea, and artificial respiration consists in mechanically and rhythmically introducing air into the proximity of the blood in the pulmonary capillaries and withdrawing it therefrom. If the temperature of the blood be maintained at about 98.4 degrees F. this mechanical part of respiration virtually insures the chemical and therefore the purpose of artificial respiration is practically accomplished by causing air to pass into the lungs and out of them alternately, regularly and rhythmically. In physiologic or natural respiration the ingress and egress of air and its approximation to the blood, and the reactions between air and blood are the same as in artificial respiration, but the chest movements are due to inward and anatomic influences. In artificial respiration the movements are imparted from without. There are, in all, only two ways in which artificial respiration can be practiced, viz., *a*, the air may be forced into the lungs, the chest walls thus forced outward and the air removed by the weight and resiliency of the chest walls, aided by compression; or, *b*, the chest capacity may be increased and diminished alternately and the air thus mechanically caused to pass in and out successively.

Now, in normal or physiologic respiration *the forcing of air into the lungs plays no part whatever*, but on the other hand *the alternate increase and diminution of the chest capacity by movements of its periphery are the sole agency in bringing air into the lungs and then causing it to go out*.

What relative part the different portions of the periphery of the chest cavity have in varying the capacity of this cavity is plain from their anatomic structure as well as from the facts of physiology. Posteriorly and anteriorly the boundary of the chest cavity is bony and virtually fixed, consisting of the thoracic portion of the spinal column behind and of the sternum before. The lateral boundaries consist of the ribs and intercostal and superimposed structures, have very restricted movements and, therefore, little effect in varying the chest capacity. Thus the posterior, the anterior and the lateral portions of the chest, so firm and so little movable, proclaim that they are mainly for the support and protection of the parts within. But inferiorly the chest cavity has no fixed limit and varies its capacity easily, greatly and rapidly, by the free movements of the diaphragm through a very wide range. Here, then, in this wonderful muscle is certainly found the leading mechanical instrumentality of respiration. With the exception, perhaps, of the heart alone, it is the most active muscle of the animal body. From infancy to old age, it rests not, slumbers not, sleeps not. If its contractions are less frequent than those of the heart, they are much more prolonged. Its allegiance to the will is less unconditional than is that of the heart. Such is its power that through reflex influence it can call to its aid costal respiration or abdominal respiration as the varying exigencies of disease or condition may require. With matchless mathematic accuracy it is attached to the liver at the one single spot that causes the downward traction of this great gland to augment to the utmost the chest capacity in the upright position and

its upward pressure to diminish that capacity when recumbency is approached. The obvious lesson of physiology, therefore, is clearly this, that the diaphragm being the foremost instrumentality in natural respiration should be employed as the leading agency in artificial respiration. But this invaluable lesson has not been left to rest on even this plain and satisfactory evidence, but has, as if in proclamation of its transcendent importance, received a most rigid demonstration from physiologic mathematics. Soon after the invention of the spirometer by Hutchinson, it was proved by actual measurement that the capacity of the chest is greater in the erect than in any reclined or in the recumbent position. Thus was demonstrated in stubborn figures a great fact for physiology, for pathology and for therapeutics. The chest is a cylinder and the diaphragm is a piston whose to-and-fro motion varies the chest capacity and causes an ingress and egress of air. In the recumbent position the liver and other contents of the abdomen press upon the diaphragm and diminish the chest capacity.

In changing from the recumbent to the erect position the pressure is gradually removed and the chest capacity increased. It is obvious that all that is necessary for the air to enter the lungs is to change the patient from a recumbent or any inclined position to the erect one, and all that is necessary to cause air to pass out of the lungs is to move the patient back from the erect to any inclined or to the recumbent position. But I have ascertained that the increase of capacity of the chest is slow and small in moving from the recumbent position to an elevation of forty-five degrees, and rapid in ascending from forty-five degrees to the erect position. It is not, therefore, essential in practicing artificial respiration to move the patient through the whole range from recumbency to erectness, but is sufficient to use only the upper half of this range, merely moving the patient from a forward inclination of forty-five degrees to the erect position and back again. Every upward and backward movement produces an inspiration, and every forward and downward movement an expiration, and the two together a complete respiratory act. By regularly repeating these acts artificial respiration is rhythmically performed and can be prolonged at will. Any one, by experimenting on himself, will find that if he leans forward from a perpendicular to an inclination of about forty-five degrees, he will mechanically and involuntarily make an expiration, and if he then straightens back to the erect line, he will mechanically and involuntarily make an inspiration. *He can not by any effort of volition prevent the result or reverse it.*

The fact of the increased capacity of the chest in the upright position, gives a solution of certain striking clinical facts. It furnishes the rationale of orthopnea and makes clear the reason why the smothering asthmatic instinctively and hurriedly leaves his horizontal posture, assumes a sitting position and, supporting his elbows on his knees, or on a table, breathes by performing in miniature the very movements above described. *He can not breathe without performing the movements, and he can not perform the movements without breathing.*

Many of those who have introduced, or have written upon methods of artificial respiration, have maintained, or at least have admitted, that in any case of collapse, the relaxed tongue and epiglottis have a ten-

dency to fall back, close the glottis and thus prevent the access of air to the lungs. Dr. Fothergill is said to have published an opinion of this kind in 1794. Marshall Hall, Mr. Bowles and Mr. Fox made some experiments, published in the London *Lancet* in 1856, which they thought proved that in the supine position the relaxed tongue must necessarily fall back and exclude the air from the trachea. But the Royal Humane Society and many of the leading medical men of Great Britain, after thorough investigation and careful experimentation, rejected the opinion of Fothergill and Marshall Hall concerning this alleged obstruction of the glottis, and laid aside the use of Hall's "Ready Method," the main merit claimed for which was the avoidance of this supposed obstruction. The whole discussion originated in a great mistake of these great men. The physiology of the closure of the glottis was misunderstood by them, though it had been clearly made out under numerous observations and experiments by Magendie and published by him in his great work on physiology, in the early part of this century. This closure is effected not by the descent of the epiglottis, but by the ascent of the glottis. Any one can satisfy himself of this by placing his finger on the upper margin of the pomum Adami and performing the act or deglutition. He will find that the glottis during the act rises at least an inch in the average person and hides itself beneath the epiglottis, effecting the closure in this way. If there is any danger therefore of this alleged obstruction of the glottis, it is least in the erect position, in which the weight of the lungs and trachea tend to keep the glottis pulled open, and greatest in the recumbent position adopted in Hall's "Ready Method" and Sylvester's method, and in all the inverted or head-down positions in which the lungs and trachea gravitate more or less toward the epiglottis.

It now only remains to note cursorily the leading methods of artificial respiration now in use, and to remark wherein each may be found in accord or not in accord with the physiologic principles presented above.

Insufflation (traditional) is performed by placing the patient in the recumbent, supine position, grasping with one hand the nose and with the other compressing the esophagus, applying mouth to mouth and inflating the lungs of the patient with the expired air of the operator, then allowing and aiding the escape of this air by opening the patient's mouth and pressing his chest, and repeating this procedure about fifteen times per minute. Objections: The recumbent position is one of small chest capacity; the air used is vitiated and non-vitalizing; the manipulations complicated, difficult and oppressive to the patient; the stomach is liable to be inflated, the air cells are liable to be damaged by stretching and even fatally ruptured, and uses of air to dilate chest contrary to nature.

LeRoy's method consists in applying a many tailed bandage around the chest of the patient in the recumbent supine position and producing chest movements by alternately tightening and slackening of the bandage. Objections: The recumbent position; the two operators required; the delay and trouble in getting bandage.

Marshall Hall's ready method (1856).—Place the patient in the recumbent position and prone. Turn the body gently but completely on the side and a little beyond and then back on the face alternately, repeat-

ing these movements deliberately, efficiently and perseveringly, fifteen times per minute. When the prone position is restored make equable but efficient pressure along the spine removing this pressure immediately before rotating back on the side. Objections: Recumbent position; small difference of chest capacity commanded by the movements, the harm that may be caused by the pressure.

Sylvester's method (1858).—Place the patient on his back with his shoulder's raised and supported on an article of dress, folded. Raise his arms upward by the sides of his head and then extend them gently and steadily upward and forward for a few moments. Next turn the patient's arms downward and press them gently and firmly against his sides for a few moments. Repeat these movements alternately, deliberately and perseveringly fifteen times a minute. Objections: The small chest capacity of the virtually recumbent position and the small variation of chest capacity produced by the movements.

H. F. Campbell's method.—Place the patient in the erect sitting position with his arms by his sides and his head erect. Raise his arms up by his head to a parallel position and exert upward traction on them. Replace the arms to their first position by the sides and press them against the chest. Repeat these movements *ad libitum*. Objections: The relatively small variation of chest capacity attainable even in the erect position steadily maintained.

Pacini's method.—Place the patient supine with shoulders and head slightly raised. With the thumbs well back on the scapular region and the fingers under the outer end of the clavicle and in the axilla, draw the clavicle and shoulder upward and backward, thus causing the pectoral muscles to elevate the chest walls. Then turn loose and let the chest walls descend, aiding by gentle compression. Repeat regularly as desired or required. Objections: The small chest capacity of the virtually recumbent position and the small variation secured by the movements.

The Michigan method.—Place the patient flat on face and stand astride of him with your face toward his head. Seize his shoulders and elevate his chest while you count slowly "one, two, three;" then allow the chest to return to its first position and press gently but firmly while you count "one, two." Repeat these movements fifteen times per minute. Objections: The horizontal position with its small chest capacity; the small increase obtainable by any elevation of less than 45 degrees, and the interference with ingress of air due to flexure forward of neck and trachea.

Shepard's method.—Place the patient on a plank or door shutter, and place the shutter or plank crosswise at its middle on a log or similar report. Then give to the patient's head and feet an alternate up-and-down movement by a like movement of the plank or shutter. This alternately increases and decreases the chest capacity, thereby promoting ingress and egress of air. Objections: Not available for infants; inconvenient and often impracticable; movements can not be carried to above 45 degrees and, therefore, can not reach the higher measures of chest capacity.

Nélaton's method (so-called).—This is a misnomer, not a method of artificial respiration, but of drainage of narcotic, anesthetic or other heavy vapors or poisonous gases from the air passages. It consists in holding up the lower parts of the body and causing the head to hang down.

Laborde's method consists in seizing the tongue by the tip, drawing it out and allowing it to recede rhythmically. This rhythmic action, by a physiologic law, tends to arouse other rhythmic movements, including the respiratory. It is not properly respiratory, but merely excitatory.

The Alabama method (1860).—Place the patient in sitting position inclined forward about 45 degrees. Move the head and shoulders upward and backward to the perpendicular position or a little beyond, taking care that the trunk is drawn up to perfect straightness and the head, neck and shoulders well up. Lean the patient forward and downward to an inclination of about 45 degrees, making cautious and reasonable compression of the chest. Repeat these movements deliberately, perseveringly and with reasonable frequency until no longer needed, or until all hope of success is lost.

Howard's method (1871).—Place the patient on his back with a roll of clothing under it, so as to raise the pit of his stomach above the level of any other part of his body. Kneel by the side of or astride the patient's hips and, with the balls of the thumbs resting on either side of the pit of the stomach, let the fingers fall into the grooves between the short ribs so as to grasp the waist. Now, using the knees as a pivot, let the operator throw all his weight forward upon his hands and squeeze the waist between them as if he wished to force everything in the chest upward out of the mouth, and deepen the pressure while he counts slowly, "one, two, three;" then suddenly let go with a final push which springs him back to his position on his knees, where he remains so long as to count "one, two." These movements are to be repeated and gradually increased in frequency from four to fifteen times per minute and continued from one to two hours, or until the patient breathes. Objections: The disadvantage of the horizontal position is present and is made worse by the sharp flexure at the waist; the great pressure at the pit of the stomach approaches in effect punches or blows on that most sensitive part, and through the injured function of the solar plexus, greatly depresses and endangers the patient.

Schultze's method.—Stand up, grasp the baby around the shoulders with your fingers posterior and thumbs anterior, meeting in the axilla, thus suspending the baby, feet downward and head upward, in front of you with its face from you, swing it rapidly through a semicircle in front of you, bringing it to rest with its buttock near your face, and after a slight pause reversing the movement. Repeat these movements as required. Objections: Requires great care and gentleness and exposes to rapid reduction of temperature.

Fell's method consists in forcing air into the lungs through the incision in laryngotomy or tracheotomy. For this purpose a bellows with tube is employed. This is designed mainly if not exclusively for surgical cases. Objections: Like insufflation it forces instead of attracting air into the lungs; increases the danger of overstrain and rupture of the air vesicles.

Keynolds' method consists in grasping the babe, with the hands just above the pelvis, the thumb being on one side, the fingers on the other and the palm applied to the sacrum and adjoining part of the spine, and thus causing the babe to hang head downward. The other hand of the operator is then glided along the babe's abdominal surface and used to apply gentle

pressure while anterior flexion is imparted to the trunk of the patient. Objections: Looks to drainage rather than to aeration and chest expansion.

Other methods are: Dyer's method; Dew's method; Forest's method.

These methods consist in varying the chest capacity and the in and out movements of the air, by manipulations and varying positions of the babe. Objections: Do not sufficiently recognize the importance of the upright position and of the agency of the diaphragm.

THE RELATION OF FOOD, AIR AND EXERCISE TO HEALTHY GROWTH AND DEVELOPMENT.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. STUVER, M.Sc., M.D., Ph.D.

Member Colorado State Medical Society (Vice President 1894); Member American Medical Association; Member International Medical Congress (Berlin); Active Member National Educational Association, etc.
RAWLINS, WYO.

"Man is what he eats," is a truism quite widely appreciated theoretically, but sadly disregarded when put into everyday practical use. Nor is this true only of the unprofessional multitude but applies with almost equal force to the great army of physicians who by their habits say in the most forcible manner, "Do not eat as I eat but eat as I tell you."

This being the case, and as an ounce of good example is worth pounds of precept, unless put into practice, let us see what influence a rational system of dietetics, pure air and plenty of exercise would have on the growth and development of the rising generation. I say rising generation because the time spent in trying to reform confirmed transgressors whose habits have become fixed by years of indulgence, is largely lost and can be spent to much better advantage in preventing the formation of bad habits by the young and helping them to overcome those which have been formed.

I shall use the term food in its comprehensive sense, including beverages of all kinds. The period of growth and development is characterized by rapid metabolism; old tissues are broken down and new ones formed more rapidly than in the mature body. These rapid changes necessitate a larger proportionate quantity of food and require that the digestive and assimilative organs be in a healthy condition so that sufficient pabulum may be furnished to supply the needs of the rapidly growing organism.

A healthy condition of the digestive and assimilative organs being one of the prime requisites to insure proper growth and development, the question naturally arises. How can such a condition be attained? Every child has the right to inherit a sound physical organization, and it should have a mother capable of furnishing it with an abundant supply of nature's true nutrient material which, if normal, far outranks all other foods for the infant, the patent baby-food manufacturers to the contrary notwithstanding. During the early years of childhood the food should consist largely of milk, be plain, nutritious and unstimulating and regular habits of eating should be established. Young children frequently suffer from thirst and should be given cold water regularly. This will often afford relief when soothing syrups fail. In this con-

nection I insist on the importance of protecting the child against stimulants and narcotic poisons of all kinds. To accomplish this the physician must throw sentiment aside and give the officious grandmothers, neighbors, *et id omne genus*, distinctly to understand that the child has some rights which should be respected and that one of these is that it should be allowed to form its own drug and poison habits. If this is not done the infant will scarcely be born before some one will suggest that an abominable decoction of herbs or a fiery dose of liquid poison in the shape of brandy and water be poured down its defenseless throat in order to keep it quiet. The natural protective instincts rebel against all stimulants and narcotic poisons.¹ To the infant or young child the first dose of an alcoholic stimulant is exceedingly distasteful, and it is only after a number of trials have been made and the natural protective instincts have become obtunded that it begins to be at all relished. The system at first surprised and insulted makes a vigorous effort to throw off the poison, but at each repetition the resistance becomes less until it finally adapts itself to the abnormal stimulation and the stimulant becomes an imperatively demanded want.

In this way an abnormal condition of the system with a craving for pungent, highly spiced foods, alcoholic stimulants and narcotics is established. This not only causes a distaste for plain and nutritious foods which are absolutely necessary to the most complete growth and development, but naturally leads to the use of tobacco in its various forms and may even-tuate in the use of alcoholic stimulants and other narcotic poisons, and finally we may have before us one of those saddest of all spectacles—a grand physical organization shattered and wrecked, a brilliant mind weakened and dethroned and a moral nature which, under other conditions, might have strengthened and elevated mankind, reduced to the lowest depths of degradation—in short an alcohol maniac, a morphin or cocain fiend or a combination of all in one.

If every physician could have these sad tragedies burned into his very soul and would then rise to the true stature of his noble calling and impress upon his friends, his patients and the world, the causes of these terrible examples which are continually falling under his observation and the means by which many of them could have been averted, we would soon see a decided improvement in the habits and health of the young.

While proper food and correct dietetic habits are of the greatest importance to the welfare and happiness of mankind, the quality of the air or gaseous food, of which we take into our lungs about one pint at each inspiration is, if possible, of still greater importance. Man can live on one meal a day and enjoy good, nay, even robust health, he can limit himself to the simplest and plainest kind of a dietary and attain a ripe old age; but let the supply of oxygen be cut off and he succumbs to carbonic acid poisoning in a very short time.

Plenty of pure air and properly regulated outdoor exercise are necessary to give nerve force; to stimulate the respiration and circulation of the blood; to develop the muscular system; to throw off or destroy the poisons constantly accumulating in the body; to strengthen and calm the mind and to produce the best moral development in persons at any age.

During the period of childhood and youth, however, when the metabolic changes are much more active;

¹ Vide Oswald's Physical Education.

when the poisons from the breaking down cells accumulate much more rapidly; when the muscular system is in an undeveloped condition and needs almost constant exercise for its proper growth; when the brain is more unstable, more easily irritated and more susceptible of being permanently injured, their importance is still much greater, and should be much more fully appreciated, than they are by the majority of people. Living and sleeping rooms should be large, well lighted and thoroughly ventilated. The covers should be thrown back from the beds, the blinds and windows opened and the pure, life-giving air and sunshine allowed to bathe the living and sleeping rooms. This may tone down the colors of beautiful carpets, but it will at the same time destroy foul exhalations and disease germs and put roses of health in the pallid cheeks of delicate children, and give a buoyancy and zest to life which can never be experienced while living in a foul atmosphere. Then, too, the school rooms in which children spend a large part of the time during the most critical years of their lives should conform to the most approved sanitary knowledge of the age. Ample provision should be made for complete drainage, the best methods of heating and lighting and for thorough ventilation should be employed. To insure a sufficient amount of oxygen all school rooms should be aired both morning and evening and at intervals during the daily sessions. This can be best accomplished by having frequent recesses during which the doors and windows are thrown open and the rooms thoroughly ventilated. President Eliot of Harvard University, President Holbrook of Lebanon, Ohio, President George L. Osborne of Warrensburg, Mo., Prof. Joseph Baldwin of Austin, Texas, and many other eminent educators advocate an open air recess at the end of each hour. Their contention is certainly based on sound physiologic and hygienic principles, and if their suggestions were carried into effect generally, there would be an immense improvement in the health, mental attainments and moral character of children all over the land.

I do not believe any one will question the fact that frequent outdoor recesses would have a most beneficial effect on the health of the pupils. Nor do I think, when the matter is carefully considered, that the conclusion will be different as to their influence on mental and moral development. It is well known that in order to insure proper development of the muscular system, the motor centers are developed early and hold a commanding position. In these centers nerve force accumulates and is stored until discharged in muscular movements, and if the attempt be made to restrain these movements beyond a certain limited time by means of the will, much nerve force which should have been used in quiet thought and study will be wasted and at the same time the physical organism will be hindered in its development. Then, too, the toxins which have been accumulating in the blood poison, weaken and tire the brain, and as a consequence mental results are unsatisfactory, because impressions made on a tired brain do not last, and the moral nature is depraved because pure and generous thoughts can not long exist in a foul body.

The Venom of Serpents.—The well known fact that the venom can be sucked out of a wound without inconvenience, is attributed by Fraser to the bile in the alimentary canal. He has demonstrated that even very small quantities of bile will render snake venom harmless.—*Nouv. Remèdes*, January 8.

THE HAIR-CELLS OF THE ACOUSTIC AND AMPULLAR AREAS OF THE EAR.

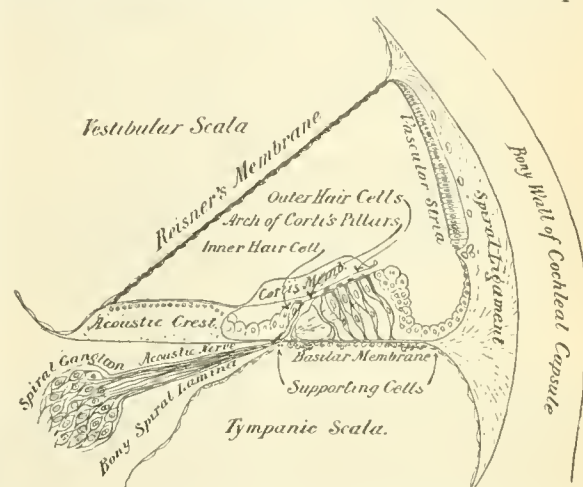

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY B. ALEX. RANDALL, M.A., M.D.

PROFESSOR OF OTOTOLOGY, UNIVERSITY OF PENNSYLVANIA AND PHILADELPHIA POLYCLINIC.

There ought to be small difficulty in demonstrating these structures to the satisfaction of the trained microscopist, who is accustomed to piece together fragmentary structures in full realization of the infrequency of ideally complete preparations; but those more engrossed in clinical medicine are less apt to obtain from our usually imperfect specimens a clear and coherent picture. The less direct method, therefore, of tracing the development of these specialized cells and their auxiliary apparatus from the primordial blastoderm, has the advantage of showing with greater ease and certainty the differentiation of these and adjacent cells of like origin; the building up of the complex structures of which they form a part and by a series of demonstrations, confessedly imperfect individually, it forms a sort of composite picture little short of the ideally complete.

Shortly after the formation of the cerebro-spinal

axis by involution of the epiblast, a similar process at each side of the head of the embryo invaginates a new bit of epiblast and forms a closed and independent sac, the otic vesicle. This elongates and throws out hollow buds, forward to form the spirally coiling cochlear tube, inward to constitute the endolymphatic duct and sac, while others starting up, back, out and down, curve to meet and coalesce into three semi-circular canals, each occupying a plane at right angles to that of each of the others. Meanwhile the central sac divides into an anterior sacculle and posterior utricle, united only by the forked endolymphatic duct, and the full-formed mammalian labyrinth is complete. Every part of its wall is made up of one or more layers of the cells which have been invaginated from the epiblast; but while it has been developing and the surrounding mesoblastic tissues have been building an elaborate set of supporting structures, the advent of nerve-fibers from the brain has enabled certain of its parts to undergo special differentiation. Such nerve-stimulus is applied to no part of the semicircular canals except the concavity of the flask-shaped ampulla which connects one end of each to the utricle. Here a crest forms upon which the cells become elon-

gated cylinders surmounted by stiff hairs, above which floats a gelatinous film, apparently an early product of their activity. These cells are demonstrably the end-organs of the nerves here distributed, which as ultimate fibrils have been traced to or into the hair-cells. Each has a thick free end, above which extend the hairs, generally agglutinated into one or more marked projections which extends well out into the lumen of the ampulla.

In the vestibular sacs, a like area is marked off, larger, flatter and less pronounced. That of the utricle is on the side nearest to the oval window, and is almost continuous with the crest of the horizontal external semicircular canal, the bases and not the hair-crowned tips of its hair-cells are turned, therefore, toward the entering waves of sound. The "macula" of the sacculus, on the contrary, is on the farther mesial wall, with the hairs of its cells directed toward the foot-plate of the stapes. Each of these areas presents cylindrical hair-cells with supporting layers beneath, probably of reserve cells to replace those which become effete. The hairs are short and separate and the gelatinous blanket which floats above these as well as all the others, is loaded with crystals of carbonate of lime, the otoliths. Here too, the nerve connections have been satisfactorily demonstrated.

This much is fairly simple, for sections can put

these parts with little confusion before you. But in the cochlea the complexity of structure and relation is far greater. Here the cylindrical tube which we have seen coiling forward, has become narrowed off from the sacculus with only the tiny "canalis reuniens" to unite them. It has become compressed into a form triangular in section, one wall forming the convexity of its turns and being in close relation always to the ensheathing mesoblastic tissues which are building the future bony "snail-shell." Within the coil a conical axis of cartilage, early ossifying, pushes forward with the fibers of the cochlear nerve and throws out about its branches a hollow shelf with spiral winding to meet the inner edge of the triangular cochlear tube. A fibrous extension of this, out beneath the under (lower-mesial) surface, forms the important membrana basilaris, the stiff radiating fibers of which probably act as the strings of a musical instrument to receive and vibrate to tones of various pitch.

Blood-supply and probably trophic nerve-fibers cause the cells of the outer wall to develop into a gland area of cylindrical cells, the stria vascularis, doubtless secreting the endolymph. The cells of the upper wall flatten into a delicate pavement upon Reissner's membrane, inconspicuous and probably functionless. It is upon the basilar membrane, however, that the really important differentiation of the neural cells takes place, for it is here that the cochlear nerve-

fibers are distributed. An elaborate supporting structure of arching Corti's pillars forms a tunnel against which lean the hair-cells, in single row to the inner, in three to five rows outward. Beyond them in each direction cylindrical and spherical cells pile up, perhaps in mere support, more probably in reserve; and above them a reticular membrane steadies them while presenting meshes for the protrusion of their ciliated ends. Over all hangs the usual gelatinous blanket. Corti's membrane, here attached at its inner margin to a toothed crest of the periosteum of the spiral lamina. Its function here as elsewhere is somewhat doubtful. It may serve to dampen the vibrations of the underlying structures as soon as cessation of the exciting sound-waves robs them of energy enough to throw it clear of such interference, or it may better be compared to the hammer which strikes upon the hairs to stimulate the nerve-endings in them. As in the piano-forte, it may subserve both purposes.

The hair cells themselves are noteworthy as being twin-structures, consisting of a fusiform Deiter's cell, below having a delicate foot implanted upon the basilar membrane in strict alignment with its fellows of the same row, and its upper process attached to the reticular membrane above and adherent to the peg-shaped hair-cell which it holds aloft. The hairs are short and stiff, set in crescentic order across the summit of each hearing-cell and protruding through the meshwork which encloses them. The fibers of the cochlear nerve enter the modiolus through a series of minute openings and to pass out between the plates constituting the bony spiral lamina. A spiral canal which they intersect in their entrance to the lamina contains a ganglionic mass with which they are in intimate relation. At the margin of the lamina they pass upward through a regular row of minute foramina, losing their sheaths as do those of the optic nerve at the lamina cribrosa; and breaking up into ultimate fibrils, they can be traced, some to the inner hair-cells, others across the tunnel of Corti's pillars to the outer hair-cells and some along the tunnel to undetected termination. It is a mooted point whether they penetrate the hair cells or only reach their exterior; but it seems relatively unimportant to trace the precise manner of their connection, so long as there is no doubt of the main fact of their direct distribution to these hearing-cells.

In spite of all attacks upon it, the theory of Helmholtz, as to the function of the cochlea in the perception of musical tones stands without reasonable alternative. The stiff radiate fibers of the basilar membrane, increasing manifold in length and tenuity from the basal to the apical turns, are like so many harp-strings (24,000, by some estimates) attuned to vibrate to sounds of every pitch audible to man. Upon them rest the hair-cells, fitted to convey to the sensorium all recognizable variations of pitch; and pathologic research enables us to predict cochlear lesions which are found in the lower or upper parts of the cochlear turns according as there was loss of perception for high or low tones. Noises of mixed or unmusical character are probably perceived in the differentiated portions of the vestibular sacculus and utricle.

As to the semicircular canals, most authorities concur in regarding their function as pertaining to equilibrium and not to audition. Clinical and experimental pathology unite to show that severe vertigo is usually the result of irritative lesions here; but that this is relieved by the advance of the condition to the destruc-

tive phase. This is the basis of Charcot's use of heroic doses of quinin for labyrinthine vertigo. As to the physiology of these canals as constituting a space organ, this has an easy explanation and demonstration, usually overlooked. Just as the water in a glass remains nearly unmoved while the glass is rotated rapidly around it, so the movements of the head rotate the semicircular canals upon their contained columns of fluid, making in one or more of the canals virtual currents in reverse of every motion. The hairs of the ampullar hair-cells instantly yield to and record these currents, their strength, direction and duration, and thus convey to the sensorium a report of every such alteration of position. The muscle-sense and the palpable recognition through the skin of the direction of gravitation aid the eyes in furnishing corroborative or corrective data, means which may at need replace the lost space-organ of the aural labyrinth in informing us of our relation to our surroundings; but so long as it is present and unimpaired, it is probably the foremost source of such information.

AIR IS FOOD; NITROGEN.

Presented in the Section on Physiology and Dietetics, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EPHRAIM CUTTER, M.D., LL.D.

NEW YORK, N. Y.

Even if unproved nitrogen is in too large proportion in the air to be inactive. When a student I heard Profs. B. Silliman Sr., Josiah P. Cooke and R. E. Rogers teach that nitrogen was negative and useless, a diluent, and that all biologic researchers maintained this position.

I could not, while respecting the dictum of these eminent men, assent to this, because nitrogen was four-fifths the bulk of air. It seemed to me that the chemists were like physicians who could not tell what was the matter, when it was patent to all that there was something wrong, and who must confess their inability in diagnosis.

Since my pupillage I have eagerly watched for evidence to support my position, and have found some that I present hereunder.

AIR IS FOOD.

This idea is over 3,000 years old. Air is indispensable to life. Eaten twenty times a minute during life. If oxygen combines with the tissues, blood for example, it becomes a normal part of the body. But oxygen is only one-fifth of the air. Nitrogen is four-fifths, and yet has nothing to do as food. This is contrary to common sense. What other food is there where only one-fifth is utilized?

Water is food. None deny that hydrogen is not food. To be sure there is more or less waste of food; but four-fifths, can this be? Are 80 per cent. of clothing, tissue, apples, beef, potatoes useless?

Again nitrogen is found in the body in large quantities. Take the proteids, C, H, O, N, S, which are the most important animal and vegetable compounds, and no phenomena of life occurs without their presence.

Subdivided.—1, albumins; 2, globulin; 3, albuminates or derived albumin; 4, proteoses (found in digestion, and in time passing into peptones); 5, soluble proteids formed by digestion by pepsin or trypsin; 6, coagulated proteids. Nitrogen is not useless and negative here certainly.

As ammonia nitrogen is found in the blood, feces, urine, sputum, horny tissue, etc. Indeed in proteids we have nitrogenous foods in abundance.

Nitrogen is active enough in the following substances: *a*, common gunpowder which is made with saltpeter, KO, NO₃; *b*, gun cotton made of cotton and NO₃; *c*, nitro-glycerin; *d*, dynamite. In these substances nitrogen is active enough to satisfy the most exacting critic.

Explosives are positive substances, acting with terrific force and violence. They are the least negative and useless substances. Let us quote from the most admirable "Standard" dictionary the list of explosives containing nitrogen; 1, gunpowder family, 25 varieties; 2, nitrate mixtures with the gunpowder, Na, Ba, NH₄, O, 66 varieties; 3, nitro-glycerin family, 121 varieties; 4, gun cotton and nitro substitution compounds made by substituting NO₃ for H, 89 varieties; 5, picric acid, C₆H₃N₃O₇ family, 20 varieties; 6, fulminic acid group = H₂CN₂O₂, 52 families; 7, Sprengel explosive family, 7 varieties; must have nitrogen, non-nitrogen explosives; KO, ClO₃ family, 78 varieties. Out of 456 explosives 378 are compounds of nitrogen, or about 83 per cent. But when it is considered that the chlorate of potassium group after explosion furnish compounds of nitrogen from the air, it may be asserted that all explosives depend on nitrogen. This is a strong showing. Explosive nitrogen in these compounds is in smaller proportions than in the air we breathe, and yet it is deemed inert in us.

BACTERIAL NITROGEN.

It has been proved that bacteria living on the roots of plants do enable the plants to assimilate nitrogen. To show that the chemists are veering to the writer's position I quote the following paragraphs from W. B. McVey, professor of chemistry, College Physicians and Surgeons, Boston.

IMPORTANT FUNCTIONS OF NITROGEN.

The great strides that have been made in the advancement of physiologic chemistry, have to my mind called for a more thorough study of the so-called indolent element, namely, nitrogen, which is usually regarded as having no particular function except to act as a dilutant or a check, so to speak, on the activity of oxygen.

Let us for a moment consider the growth and development of cell life, its causes and effects. It is a well known fact that a complex form of matter was necessary before life could appear and before the physical agencies of nature could elaborate the substance in the form of what we call protoplasm, which is the same in all animal bodies, to-wit, a viscous jelly-like matter possessing motion, secretion, digestion, excretion and reproduction.

As we ascend from the first cell of protoplasm in the scale of vitality, we reach that degree where the crystallizable matter of the higher species is required, so we find intimately combined in the albuminoid principles, the colloid (gluey) and crystalloid (crystal forming). The colloids of protoplasm are proteids and permeate the crystalline part of the animal body, and in presence of the mineral matter therein continue the chemical change going on.

The crystalloids go to build up the fiber of the body. The colloid institute and continue the power of its reproduction, and carbon and phosphorus being present in the former, life depends upon a certain chemical nucleus in order to associate itself with matter. Every living thing requires this nucleus.

Heat, light, electric and mechanical power and magnetism are the agencies acting upon this nucleus through the agency of nitrogen, causing and bringing by colonization the many kinds of animal bodies into existence.

The spectroscope shows that sulphur and phosphorus are compounds and not elements; and that phosphorus is produced from a differentiation of sulphur by the action of chlorine and hydrogen. It is the potential action of nitrogen upon this that causes the chemical and physical changes, and starts the process of ultimate production of protoplasm and afterward animation. It is brought about by action of sunlight upon the phosphorus contained in the nucleus, attracting the electric energy that is pent up in the so-called useless nitrogen. Then by the aid of magnetic iron, carbon and amorphous matter draws forth the electric energy from the earth through phosphorus as a nucleus, which starts the oxygenating process.

Nature requires motion in animal bodies before locomotion can take place, the force and power of such motion being supplied from the food and air.

If it were not for nitrogen locomotion could not take place. Pent up it is more electric potentiality than any other element in nature. This potentiality institutes the power of locomotion in all animals either by direct or indirect transmission and modification.

It is not the vivifying power of oxygen but the explosive power of nitrogen that originates locomotion, and by its rhythmic explosion the respiratory process originates and continues, which is the cause of that motion in nutrition.

Nitrogen, which is supposed to be the most indolent thing in nature, is indeed the most powerful and essential to the movement of all bodies, since explosion depends upon the constant instantaneous liberation of nitrogen, it also acts as a controlling agent to prevent the too rapid reduction of the tissues. It controls the chemical action of respiration.

Nitrogen enables the body to perform its functions to the end of the organizing process, which culminates in the separation of the vital from the chemical.

Conclusion.—If life is made up of motions and emotions, and if nitrogen is such a kinetic agent actual and potential as has been pointed out, then it appears reasonable that it is not a mere diluent and negative in human food.

THE ACTION OF ODORS, PLEASANT AND UNPLEASANT, UPON BLOOD FLOW.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June, 1-4, 1897.

BY EPHRAIM CUTTER, M.D., LL.D.

NEW YORK, N. Y.

In 1859, Alvan Clarke made me a laryngoscope. After 1862 I studied auto-laryngoscopy and auto-rhinoscopy. I took the first photographs in this continent of the living larynx in 1866; copies of these are deposited in the United States Army Medical Museum, Washington.

I was and am able to demonstrate to myself, my posterior nares, either Eustachian orifice, turbinated bones, dome of pharynx, vomer, etc.

Among the physiologic studies made in 1866 was the action of cologne, roses, camphor, ammonia, sulphur fumes, etc., upon the erectile tissues of the tur-

binated bones. They were of a pale ashy white color ordinarily. A few whiffs through the nose of any of these odors increased the blood flow and produced immediately a livid injection and turgescence of the erectile tissues on the turbinated bones, that stood out as clearly and positively as the erection and turgescence of the livid wattles of an excited turkey cock. It was a surprise to find that these pleasant and unpleasant odors acted alike. I found in the case of sulphur fumes, that when I could not inhale them from a match ignited before my face, with open mouth, I could breathe readily through my nose. This proved that the erectile turgescence availed to remove the sulphurous oxid so as to have respirable air and protect the inhaler.

The morphology of nasal excretions excited by the morphologic elements found in the impure air, also proved the value of the irritated turgescence mucous membrane of the nares in arresting foreign bodies borne in on the atmosphere.

ARROW-ROOT, CASSAVA AND KOONTI.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY A. T. CUZNER, M.D.

GILMORE, FLA.

ARROW-ROOT.

Arrow-root (*Maranta Arundinacea*) is the name the Indians of America gave this plant. In German arrow-root is called *pfeilwurz*, *pfeil* meaning arrow, and *wurz* meaning root. It is the English name of the botanical genus *maranta*, the type of the endogenous order *Marantaceae*, called by Lindley in his "Natural System of Botany" the arrow-root tribe, but altered in his "Vegetable Kingdom" to *maranta*.

The flowers of this plant are in long, close spike-like panicles with irregular corollas, each having a single perfect stamen with half another. The veins of the leaves run out obliquely from the midrib to the margin. The root is a fleshy corm which when washed, grated and strained, and again repeatedly washed, furnishes the substance so much prized as food for invalids.

The starch extracted from the rhizomes of different *maranta*, and imported into the United States and England, takes the name of the place from which it comes. Thus we have Bermuda arrow-root, East Indian, St. Vincent, Natal, etc.. True arrow-root is without doubt the best of all the starch foods to be obtained in the market; hence it is largely adulterated with other and inferior starches, which adulteration is readily detected under the microscope. In England attempts have been made to call every prepared starch arrow-root bearing the slightest resemblance to the true *maranta*. This has failed there owing to the passage of the "Adulteration Act."

It is now understood by public analysts, magistrates, etc., that arrow-root must consist entirely of the starch extracted from the rhizomes of a *maranta*, and any admixture of potato or other starch is regarded as an adulteration. Arrow-root is much more used in England than in the United States, both as ordinary food and as a preparation for the use of invalids and infants. In the former country they prepare what is called white soup by the addition of arrow-root.

The price of arrow-root in England ranges from 13

to 50 cents per pound. It is not much used in the United States. This may be owing to the difficulty of obtaining a pure article, and therefore the true value of arrow-root is not properly appreciated.

It is an excellent material to mix with cow's milk in order to cut up and dilute the excessive proportion of casein. Human milk contains but 1 per cent. of casein, while that of cow's contains 4 per cent.

As a food for young children (and even infants) I prefer arrow-root to barley. Arrow-root should be more largely used in inflammatory diseases of the alimentary canal. It is by far the most palatable of all the different starch preparations.

Figure 1 represents an arrow-root plant, with A, an enlarged drawing of a rhizome. These drawings were made by the writer from a specimen plant of Bermuda arrow-root grown on his own place in Florida.

The drawing of starch cells (Fig. 2), was made from sample of starch obtained from the roots and viewed under the microscope.

Fig. 1.—Arrow-root.

The plant is easy to cultivate. In fact once planted it is very hard to get rid of, as the smallest piece of root left in the ground multiplies rapidly.

The process of extracting the farina is very simple, and the ordinary housewife finds no difficulty in obtaining the starch from the fresh roots. These are first washed. They are then grated on an ordinary grater into a pan or vessel of water. The pulp is thoroughly stirred in the water in order to separate the starch cells from the fibrous portion. The vessel containing the grated roots is now set aside for a short time to allow the starch cells to settle. These cells being heavier than the fibrous portion, sink to the bottom. The water containing the debris can now be poured off and fresh water added. The starch and fresh water are well mixed together and then set aside for the starch to settle as before. This washing process may be repeated a number of times. The more thoroughly the starch is washed the purer it becomes.

Owing to the limited demand for arrow-root the plant is not cultivated much in Florida. Many of the negroes raise it on their small farms in limited quantities in order to obtain starch for laundry purposes. The supply can, and doubtless will be, always equal to the demand.

Fig. 2.—Starch cells, Arrow-root.

CASSAVA.

"Cassava" belongs to the family of euphorbiaceæ, and the bitter variety of Brazil (*Manihot utilisima*) is said to contain a large per cent. of hydrocyanic acid.

The sweet variety is indigenous to both Africa and the West Indies. From the last it was introduced into Florida under the name of "cassava" (also aboriginal).

The wild variety was eaten by the South American and Caribbean Indians centuries before this country was discovered by Europeans. In Brazil today mandioca is as much in use as wheat and corn in the United States.

The Indian mode of preparing the roots for food, in vogue nobody knows how many centuries before the first Spaniard or Portuguese came to the country, has not been much improved upon. With a shell or a rude grater made by setting a small sharp stone into a bit of bark, the roots are scraped to a fine pulp. The pulp is then rubbed between stones until all the poisonous juice is squeezed out, and the remaining moisture evaporated by exposure to the fire or hot sun. During the drying it is stirred or broken into coarse grains. This is the farina or mandioca flour, the bread of the rural Brazilians. The Portuguese invented mills for preparing mandioca, not unlike Yankee cider presses. The roots are first washed and then the rind is removed. Then the pieces are held in the hand, in contact with a circular grater.

Fig. 3.—Starch cells from Cassava.

The pulverized material is placed in sacks, several of which are subjected to the action of a screw press, or they are suspended from a pole and weights attached to them. These processes cause the expulsion of the poisonous fluid. The mass thus treated is next beaten fine in a mortar. It is now transferred to open ovens

and stirred constantly until thoroughly dry. When properly prepared, the farina is very white and beautiful.

Mandioca is said to have medicinal virtues. A poultice made of the grated pulp and moistened with the juice, is considered a cure for abscess. A drop or two of the poisonous juice is administered for tapeworm. But it is principally with the sweet variety or true cassava grown in Florida that the reader is most interested. It is undoubtedly destined to take high rank as a food plant not only on account of its richness in starch, but also from its enormous yield under proper cultivation. It is said to yield 600 bushels per acre, while sweet potatoes (or yams) yield but 500 under the same conditions.

The following is the United States Department of Agriculture analysis:

Water	70.44 per cent.
Ash57
Oil and fat38
Glucose28
Sugar	5.19
Crude fiber	1.19
Nitrogenous bodies	1.03
Starch	21.24

Fig. 4.—Cassava Plant.

Sweet cassava (*Manihot aipi*, Pohl.) abounds in a milky non-poisonous juice. The roots are grated the same as the bitter variety and the juice extracted.

The resulting farina consists largely of broken cell-walls containing a certain quantity of starch. The farina or meal is dried on plates, and is made into cassava cakes. The liquor, which passes away under pressure, contains a large amount of starch. This may be recovered if the liquor is allowed to stand until settled, when the liquid portion can be poured off, and the starch reclaimed. (Fig. 3.)

In the illustration it will be seen that the starch cells are muller-shaped. Tapioca is prepared by heating moistened cassava starch on hot plates.

This process alters the starch cells, causing them to swell up, many of them bursting and agglomerating in small irregular masses. Tapioca is not pure starch. By the process adopted part of the starch is

changed into gum; there are also traces of sugar to be found in tapioca.

In the liquor that is poured from the deposited starch much gum and some albumin may be obtained.

The illustration shows the entire plant. It is not propagated either from the root or seed. Pieces of the stalk are planted and from the buds grow the future plants. In this way sugar cane is also propagated.

KOONTI.

This plant (*Zamia integrifolia*) is a native of South Florida, and is called "Indian Bread-root." In its foliage it bears a resemblance to the palm and tree fern. In affinity it is nearer the latter than the former. Figure 5 represents the appearance of the plant. Its root is the edible portion.

When the poor whites on the east coast are greatly in need of money they go to the woods and dig koonti, finding a ready market for the roots. Indeed, it is the sole occupation of many people. The roots are not cultivated, as they grow wild in great abundance. A very fine quality of starch and tapioca is manufactured from them, which may be found at all times in the Key West market.

Figure 6 shows the appearance of the starch cells of

Figure 5.

koonti. They are muller-shaped, like those of cassava, but smaller. The starch is said to be equal to the best Bermuda arrow-root, and lately its worth as an article of commerce has been fully recognized in Florida. There are a number of factories for its preparation in Southern Florida. A correspondent of the United States Agricultural Department writes: "I ate of a koonti pudding, at Miami, and can say that, as it was there prepared and served, with milk and guava jelly, it was delicious."

The unique industry (in the more limited sense of the word) of the Seminole is the making of the koonti flour. The Indian process is this. The roots are gathered, the earth is washed from them, and they are laid in heaps near the "koonti log." The koonti log, so-called, is the trunk of a large pine tree, in which a number of holes, about nine inches square at the top, their sides sloping downward to a point, have

been cut side by side. Each of these holes is the property of some one of the squaws or children of the camp. For each of the holes, which serve as mortars, a pestle made of some hard wood is furnished.

The first step in the process is to reduce the washed koonti to a kind of pulp by chopping it into small pieces and filling with it one of the mortars, and pounding it with a pestle. The contents of the mortars are then laid upon a small platform; each worker has one. When a sufficient quantity of the root has been pounded, the whole mass is thoroughly saturated with water, in a vessel made of bark. The pulp is then washed in a straining cloth, the starch of the koonti draining into a deer hide suspended below. When the starch has been thoroughly washed from the mass, the latter is thrown away, and the starchy sediment in the water left to macerate. After some days the sediment is taken from the water and spread upon palmetto leaves to dry. When dried, it is a yellowish white flour, ready for use.

Figure 6.

In the factories this process is substantially followed but with improved appliances. The chief variation being that the koonti starch undergoes several successive macerations, thereby making it purer and whiter than the Indian product.

The koonti bread made by the Indians is of a bright orange color. It is rather insipid, though not unpleasant to the taste. It is made without salt. Its yellow color is due to the fact that the flour has had but one maceration.

A STUDY OF THE DEFORMITIES OF THE JAWS AMONG THE DEGENERATE CLASSES OF EUROPE.

BY EUGENE S. TALBOT, M.D., D.D.S.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.
CHICAGO.

The Twelfth International Medical Congress in Moscow, afforded me a long-sought-for opportunity, not merely to visit Russia, but also to cover nearly all the countries of Europe. In visiting the various cities I made special observations of the degenerates in each of the various institutions for the defective classes. The objective points of interest were the prisons, insane hospitals, schools of idiocy, foundlings' homes, etc. The features of the soldiers, police and cabmen, as well as the citizens themselves, were incidentally noted for the purpose of comparison. These observations, however, were for an entirely different purpose, the object of this paper being to record results as to the deformities of the jaws and teeth of the mature degenerate classes.

In a prison in Athens containing 452 convicts, not a single V or saddle arch was found, although slight irregularities of the teeth due to local causes were observed. Arrest of the lower jaw, however, was the

rule, which together with the recession of the forehead gave to the individual an idiotic appearance. Irregularity, in the relation of the upper to the lower jaw due to excessive and arrest of development, was very common. The third molars, upper and lower, were present, but the vault was lower than the average.

In a Greek insane hospital (idiots are here confined with the insane), in Constantinople, of 332 inmates (equally divided as to sex) only one case of V-shaped arch was noted. The vaults were low, upper jaws large and full, but 48 per cent. of the lower jaws arrested, the third molars normally developed.

In an Armenian insane hospital (idiots are here confined with the insane) in Constantinople, of 250 inmates (175 males, 75 females) there was one partial V-shaped arch, the third molars normal, and the lower jaw arrested in 18 per cent. There were many mongoloid faces.

In the Vienna Insane Hospital, among 326 insane and idiots there were 4 partial V and 1 saddle-shaped. The third molars were normally developed in 311 cases.

In a prison in Moscow, with 2,000 convicts (247 of which were in the hospital) there were no contracted jaws nor irregularities of the teeth. The jaws were very large and vaults low. In the Moscow Reform School, 112 boys were ranging from 10 to 18 years. Three had partial V-shaped arches; no saddle-shaped arches. The jaws, as a rule, were large and broad with low vaults.

In a Moscow insane hospital with 400 patients, of which 12 were idiots, no contracted arches were observed. The jaws were large and broad with low vaults.

In the Stockholm Insane Hospital, with 270 patients, 6 V-shaped arches, 12 partial V, 4 semi V, 23 saddle-shaped, 4 partial saddle, 11 excessively developed upper jaws, 3 excessively developed lower jaws, 9 hypertrophy of the alveolar process, 42 missing third molars, 6 missing laterals were noted. Deformities of individual teeth were numerous.

The School of Idiocy of Stockholm with 120 inmates, 80 boys, 40 girls, gave the following results:

BOYS.	GIRLS.
14 normal jaws.	15 normal jaws.
12 V-shaped.	1 V-shaped.
10 partial V-shaped.	5 partial V.
4 semi V-shaped.	5 semi V.
8 saddle-shaped.	8 saddle-shaped.
1 partial saddle.	1 semi-saddle.
2 semi-saddle.	6 macrocephalic.
12 macrocephalic.	4 microcephalic.
5 microcephalic.	

Thirty-two boys and fourteen girls had hypertrophy of the alveolar process on the upper jaw. One boy, aged 13 years, who was able to take care of himself, had a head thirty-two inches in circumference, one of the largest on record. The prison at Hamburg had 1800 convicts. Large, well-developed jaws were the rule. Asymmetry in development, however, was frequently noticed as well as other stigmata.

The School of Idiocy at Hamburg had 600 children, 396 boys, 204 girls, and gave the following results:

BOYS.	GIRLS.
62 normal jaws.	28 normal jaws.
12 V-shaped.	4 V-shaped.
16 partial V.	7 partial V.
8 semi-V.	3 semi-V.
4 saddle.	1 saddle.
3 partial saddle.	1 partial saddle.

2 semi-saddle. 3 semi-saddle.
46 hypertrophy of alveolar process. 25 hypertrophy of alveolar process.
3 macrocephalic. 5 macrocephalic.
4 microcephalic. 2 microcephalic.

One boy of 13 years had an excessive lower jaw, being one and a half inches beyond normal upper, a most remarkable case.

In the Insane Hospital and School of Idiocy at Amsterdam, there were 1330 insane, 255 idiots. In the insane no contracted arches were found. Vaults were low; 67 had hypertrophy of the alveolar process. No third molars were missing.

IDIOTS.

116 males:

1 V-shaped.
3 partial V.
1 semi-V.
1 saddle.

139 females:

1 V-shaped.
2 partial V.

There was hypertrophy of the alveolar process in nineteen. The vaults were low and jaws well developed.

The School of Idiots, Paris, 667 inmates, 500 boys, 167 girls, gave the following results:

BOYS.

1 V-shaped.
40 partial V-shaped.
2 semi-V.
2 saddle.
1 partial saddle.
4 semi-saddle.
7 hypertrophy of alveolar process.

GIRLS.

1 V-shaped.
6 partial V-shaped.
1 semi-V.
8 saddle.
2 partial saddle.
1 semi-saddle.
4 hypertrophy of alveolar process.

The vaults were low.

Having permits to visit the following prisons in Paris, Ci-aprie, Le Depot, Grande Roquette, Mazas, La Santé, St. Pélagie and San Lazan, after examining the convicts in the first four, aggregating 2600, I abandoned the task, since no deformities of the jaws of special value were observed.

In England I examined the following public asylums: 1. Earlswood, Red Hill, Surrey. 2. Darenth School for Children. 3. Darenth School for Adults, Hanwell Hospital for the Insane and the following private institutions: 4. Mrs. Langdon Down. 5. Dr. Shuttleworth. 6. Dr. Beach. A day was spent at the Criminal Insane Hospital, Broadmore. Fully one-half the inmates were so violent that the task was given up. Enough, however, was observed to warrant my stating that fully 80 to 85 per cent. had marked deformities of the jaws and teeth.

Hanwell Hospital for the Insane, Southall, has 2080 patients, mostly of the dependent class, who went insane after maturity; hence the class of deformities which are under discussion were not common. Hypertrophy of the alveolar process and excessive and arrested development of the jaws were, however, frequently noticed. Stigmata of degeneracy of head, face, eyes, ears, body, hands and feet were the rule.

Earlswood Idiot Asylum, Red Hill, Surrey, contained 670, of which 400 were boys and 270 girls.

BOYS.

31 normal jaws.
108 V-shaped.
69 partial V.
11 semi-V.
19 saddle.
27 partial saddle.
13 semi-saddle.

GIRLS.

24 normal jaws.
67 V-shaped.
86 partial V.
24 semi-V.
8 partial saddle.
23 semi-saddle.
1 cleft palate.
87 Marked arrest of upper jaw.
21 marked protrusion of upper jaw.

104 Marked arrest of upper jaw.
64 marked protrusion of upper jaw.

11 marked protrusion of lower jaw.
306 marked arrest of lower jaw.
46 lateral incisors arrested.
28 lateral incisors lost.
180 third molars lost.
160 showed malnutrition of teeth.

1 marked protrusion of lower jaw.
237 marked arrest of lower jaw.
30 lateral incisors arrested.
16 lateral incisors lost.
85 third molars lost.
78 showed malnutrition of teeth.

Darenth School for Idiots, Dartford, Kent, had 1000 inmates, 640 boys and 360 girls.

BOYS.

150 normal jaws.
143 V-shaped.
140 partial V.
105 semi-V.
35 saddle.
20 partial saddle.
10 semi-saddle.
450 marked arrest of upper jaw.
150 marked protrusion of upper jaw.
23 marked protrusion of lower jaw.
600 arrest of the lower jaw.
68 lateral incisors arrested.
42 lateral incisors lost.
388 third molars lost.
150 hypertrophy of the upper jaw.

GIRLS.

90 normal jaws.
118 V-shaped.
80 partial V-shaped.
65 semi-V.
8 partial saddle.
20 semi-saddle.
310 marked arrest of upper jaw.
90 marked protrusion of upper jaw.
9 marked protrusion of lower jaw.
340 arrest of the lower jaw.
32 lateral incisors arrested.
19 lateral incisors lost.
111 third molars lost.
90 hypertrophy of the upper jaw.

Darenth School for Adults (idiots), Dartford, Kent, contained 1050 inmates, 450 males, and 600 females.

MALES.

60 normal jaws.
105 V-shaped.
93 partial V.
53 semi-V.
31 saddle.
5 partial saddle.
295 marked arrest of upper jaw.
162 marked protrusion of the upper jaw.
8 marked protrusion of the lower jaw.
409 arrest of lower jaw.
48 lateral incisors arrested.
37 lateral incisors lost.
442 third molars lost.
58 hypertrophy of upper jaw.

FEMALES.

40 normal jaws.
177 V-shaped.
121 partial V.
79 semi-V.
8 partial saddle.
10 semi-saddle.
436 marked arrest of upper jaw.
209 marked protrusion of the upper jaw.
17 marked protrusion of the lower jaw.
580 arrest of lower jaw.
72 lateral incisors arrested.
62 lateral incisors lost.
597 third molars lost.
36 hypertrophy of upper jaw.

Of the children, 576 boys and 282 girls showed malnutrition *in utero*. Of the adults, 396 males and 578 females showed malnutrition *in utero*.

Mrs. Langdon Down's School for Idiots, Normansfield, Hamptonwick, contained 147 inmates, 97 boys and 50 girls.

BOYS.

12 normal jaws.
36 V-shaped.
20 partial V.
15 semi-V.
9 saddle.
13 partial saddle.
28 semi-saddle.
86 arrest upper jaw.
92 third molar missing.
16 lateral incisors missing.
46 teeth showing arrest and grooves.
19 hypertrophy of alveolar process.

GIRLS.

5 normal jaws.
10 V-shaped.
9 partial V.
12 semi-V.
7 saddle.
1 partial saddle.
16 semi-saddle.
45 arrest upper jaw.
47 third molar missing.
8 lateral incisors missing.
21 teeth showing arrest and grooves.
7 hypertrophy of alveolar process.

Of the twelve normal dental arches (males) seven were hypertrophied. Of the five normal dental arches (females) three were hypertrophied.

Dr. Shuttleworth's Private Idiot School, Richmond Hill, had twelve boys and girls. There was one normal jaw, but no laterals. There were two V-shaped,

five partial V, one semi-V, two partial saddle, and one semi-saddle shaped jaw. Four had hypertrophy of alveolar process; nine had notched and pitted teeth, and all high vaults. These patients were too young to decide as to the number of third molars, but five had one or both laterals missing.

Dr. Fletcher Beach, Winchester House, Kingston Road, had thirteen patients: Three V-shaped, eight partial V and one semi V-shaped jaw; six hypertrophy of alveolar process; eight had notched and pitted teeth; all high vaults. These patients were also too young to decide as to the number of third molars. Four had one or both laterals missing.

These reports are tabulated in the order in which they were made. They show a gradual increase degeneracy from the examinations made in Greece to those in England. It will also be noticed that the deformities of the jaws and teeth are more numerous among the better classes, such as are shown in the private institutions of Mrs. Langdon Down and Drs. Shuttleworth and Beach, than those of the poorer classes in the public institutions of England.

From examinations previously made in Spain, Italy and Switzerland among the degenerate classes, a very small percentage of deformities of the teeth and jaws were found. As compared with the American born degenerate classes, the percentages are greater than those of the Latin races, and the Slavs, Germans, Austrians, Danes and Dutch, but less from 25 to 30 per cent. than the Swedes and English.

These observations have proven to me what I long ago suspected from my studies of the degenerate classes which have come to America, and which fill our public charitable institutions as well as our prisons, that the higher the intellectuality the greater the degeneracy of the jaws and teeth.

SOCIETY PROCEEDINGS.

The Mitchell District Medical Society of Indiana.

Semi-annual meeting held at West Baden Springs, Dec. 27, 28 and 29, 1897.

The meeting was called to order by Dr. J. GARLAND SHERRILL, the president. After transacting routine business, the first paper, entitled

INJURIES OF THE HEAD,

was read by Dr. JOHN F. POTTS of Bloomington, Ind.

After some general observations on the subject of extensive depressed fractures of the skull, Dr. Potts illustrated his point by reciting the case of a man 53 years old, who, Jan. 22, 1897, sustained a fracture of the left parietal and temporal bones, which were crushed in, involving the extremity of the frontal bone and leaving a large opening through which a considerable mass of brain substance protruded. Careful removal of the depressed bone left a very large area of exposed brain substance exuding through the lacerated meninges. The patient recovered consciousness and did fairly well until February 26, when he was seized with a severe chill. On the night of the 27th convulsions came on. March 1 a large mass protruded through the opening. The most prominent part of the swelling was punctured by the exploring needle, without results. The patient's condition was such that incision was deemed necessary to determine the cause of the swelling; a large amount of pus escaped and the convulsions ceased. From this time on the patient advanced in convalescence, finally making good recovery. The left eye was blind and the pupillary reflex presented a yellowish pink color. The patient claimed to have perception of light. Dr. Potts thought injuries of this character, in which the skull was crushed in, although involving one whole side of the head, as this did, and making it necessary to take out an enormous amount of the cranial wall, frequently resulted fatally for the lack of complete removal of depressed bone, regardless of the area involved. He wished to know if any of the members present

could account for the loss of sight and the peculiar pupillary reflex in the left eye.

Dr. PEINGST felt satisfied that the injury of the eye was due to embolism in the choroidal vessels, causing inflammation of the vitreous humor.

Dr. WM. V. MORGAN thought septic infection sufficiently explained the condition described. General inflammation of all the structures of the globe, he had no doubt, resulted from infection of the wound in the brain. Dr. Morgan pointed out the difficulty in ordinary cases of severe injuries to the head in determining the presence of fracture of the bone, because of the hard, sharply defined, marginal outline of the site of the injury. In severe contusions of the scalp this sharply defined outline is so abrupt and so hard to the sense of touch as to present all the physical characteristics of depressed fracture. He thinks great danger of confining infectious matter may result from too early suturing of the dura mater. Secondary hemorrhage is another source of danger. He recently had three cases of depressed fracture, with loss of brain substance, in all of whom serious hemorrhage was present, yet recovery was secured by the prompt control of the hemorrhage by packing with iodoform gauze and maintaining ample drainage. In all of these cases small abscesses requiring puncture occurred. He thinks Rolando's fissure the frequent site of hemorrhage. Large clots forming in this fissure require to be turned out and in order that it may be properly exposed it is of the first importance that it should be accurately located externally. His method of locating the fissure of Rolando consists in taking a tape, with which he measures from the most inferior part of the external auditory meatus, in a directly vertical line over the sagittal suture, and then placing the lower end of the tape in the nasal notch of the frontal bone, he extends it directly back along the median line, resting the superior end of the tape, which marks the distance from the inferior auditory meatus to the median line, firmly upon the head, the lower end is now swept to the outer border of the malar bone; the upper three-fifths of the tape then lies over Rolando's fissure.

Dr. J. GARLAND SHERRILL considers it the first duty of the surgeon to ascertain the extent and character of the injury, without waiting for symptoms of pressure. Delayed exploration allows time for organic changes to take place in the brain substance, which leads to cicatricial formations, followed by epilepsy, and sometimes even more serious results.

Dr. CHARLES P. COOK of New Albany reported the case of a man who had been sandbagged and in whom no symptoms of local injury, excepting swelling, existed. The sharp marginal outline of a contused scalp was absent. The nature of the injury was completely masked until symptoms of compression became marked. Operative interference was not permitted and after a tedious and prolonged course of medication the patient made final recovery.

Prof. WM. V. MORGAN cited the rules laid down by Dr. Agnew for determining injuries to the brain when no objective symptoms are present. He then related the important features of a case of laceration of the sigmoid portion of the lateral sinus, in which early operation was done. The patient was a boy who had been kicked in the head by a horse. Foreign matter was carried into the wound. On elevating the depressed bone a frightful hemorrhage occurred, which was controlled by packing with iodoform gauze. On the third day, when the packing was removed the hemorrhage recurred and death seemed imminent. Repacking, however, finally succeeded in arresting it. On the seventh day, when the second packing had been removed, it was found that the lateral sinus had been cut half in two.

Dr. E. P. EASLEY of New Albany saw a case with Dr. Chas. Cook in which the fracture extended below the ear, involving the base of the occipital bone. The depressed bone was carefully removed, posteriorly below the mastoid and the patient made complete recovery.

Dr. SHERRILL thinks shaving the head removes the chief obstacle to the discovery of objective signs of fracture, where the soft parts remain unbroken.

Dr. A. W. BRAYTON recited Phelps' published list of 300 detailed cases, in nearly all of which symptoms of depression lead to the localization of the site of injury, yet in some cases this is not possible. In a case where no symptoms of external injury existed, the patient died from pressure of a blood clot.

Dr. SHERRILL reported an interesting case of death, resulting from cerebral apoplexy, due to atheroma, in which a fall was supposed to have produced concussion with fatal result, when, in fact, loss of consciousness actually preceded the fall.

Dr. EASLEY of New Albany reported a case where a blow on the head, which produced no external sign of injury, was followed by hemorrhage from the middle meningeal artery, resulting in death.

DECEMBER 28, 9 A.M.

Dr. WM. D. PENNINGTON of West Baden read a paper on "Acute Gastritis." In a majority of such cases the more serious structural changes take place in the pyloric region. Nearly all cases of acute gastritis are due either to microphytic causes, or the presence of insoluble matter or concentrated alcoholic drinks. The differentiation is generally sufficiently easy by the aid of microscopic analysis. Apomorphia and syrup of ipecac are the best emetics in cases of retained insoluble matter. In the treatment of all forms of acute gastritis he esteems saccharated mercury, limiting the patient's diet to skimmed milk as long as any inflammation is present.

Dr. SYMON P. SCHERER of Indianapolis considered the early employment of lavage most important. This should be repeated at least once per day, with sterile water containing a small quantity of bicarbonate of sodium. At first the stomach should be washed two or three times to insure thorough emptying and cleansing. In cases of ectasia he finds ingesta remaining in the stomach for twenty-four hours. He insists upon the value of lavage in all cases of gastritis and in atonic dyspepsia, with or without gastralgia. He would not, in ordinary cases, allow the patient to use the stomach tube without the presence of a trained nurse or the physician himself.

Dr. J. GARLAND SHERRILL insists upon some discrimination as to the cause of the gastritis. He maintains that the same treatment can not be applied in all cases of microphytic inflammation and those arising from caustic alkalies. In the latter class of cases no food should be introduced into the stomach, feeding should be done entirely per rectum. Lavage in such cases must necessarily aggravate the patient's discomfort. He thinks medicinal treatment in such cases should be limited to fluids that have some local anesthetic or anodyne properties.

Dr. E. P. EASLEY would not use the tube in acute cases, after once emptying the stomach. He does not doubt the value of repeated lavage in chronic catarrhal gastritis. The apparatus, however, and its mode of use are obstacles to the employment of that method in private practice. Poor people can not afford the apparatus and no untrained person can be trusted to use it.

Prof. WM. V. MORGAN of Indianapolis suggests that a perfectly satisfactory apparatus can be constructed of a plain piece of rubber tubing, by first trimming and then sandpapering the end of it so as to round it and make it perfectly smooth. After carefully washing off any adhering foreign matter that may have become attached to the rubber in the process of smoothing it, attach a common funnel to the other end of the tube. The rubber should be three feet in length with an aperture of one fourth of an inch. In many chronic cases the repeated employment of lavage is of the greatest service.

Dr. WM. D. PENNINGTON fully endorsed the device of Professor Morgan.

Dr. ADOLPH PFINGST of Louisville read a paper on "Middle Ear Complications in the Course of Measles." He reported the case of a child in whom sudden high temperature continued for several days, and which had been preceded by very slight discomfort of one ear only. When he was called to the case, both external drumheads were swollen and bulging. Hearing by the watch test = 4 xxx. Hot poultices resulted in the rupture of both membranes and the free discharge of pus. The absence of pain in otitis media, occurring in the course of measles, seems to be as commonly observed as the sudden onset of high temperature. In Bezold's cases many died without having such symptoms as to attract attention to the ear, yet autopsy showed indurated lining of the drum cavity, and in some the ear drum was filled with pus. Dr. Pfingst concurs in the opinion that infection is sometimes carried by the air into the tympanum; at other times tympanic disease is the result of infection by contiguity of structure. He believes that measles rarely runs its course without provoking some form of otitis media, the purulent form being the most frequently observed.

Dr. ULRICH H. HOX of Bloomington called attention to the fact that the eruption of measles is present in all the mucous membranes as well as the skin, and he has no doubt it is present in the middle ear as well as the fauces, where it is always well marked. He has often observed suppurative otitis appearing simultaneously with the decline of the eruption in the skin.

Dr. JOHN F. BARNHILL of Indianapolis called attention to the unfortunate failure to recognize the ear complication sufficiently early to prevent suppuration, and such deep seated organic changes as to permanently impair the hearing. The narrow Eustachian canal is early closed by accumulating mucus, which will soon be observed to undergo suppurative changes. He thinks shutting out the circulating current of air nearly always leads to suppuration of the retained mucus in cases of measles.

Dr. PFINGST accepts Dr. Barnhill's explanation of the cause of suppuration.

Dr. JOHN F. BARNHILL read a paper on "Extrapulmonary Coughs." Reflex causes are found in impacted cerumen, eczema of the external auditory canal, nasal obstructions, diseases of the pharynx, and a dripping from the vault of the pharynx into the larynx. The ear, nose and pharynx must be explored in all cases, searching for retained matter, inflamed areas, morbid growths, enlargement of the inferior lobes of the tonsils, concretions in the upper lobes of the tonsils, and various conditions of the epiglottis. Sometimes cervical tumors pressing on the vagus excite cough. He related cases due to deformities of the septum narium, with adenoid growths in the posterior nasal spaces; small tumors on the base of the tongue which irritate the crest of the epiglottis; elongated uvula; and some cases of neurotic persons in whom no local morbid conditions could be discovered.

Dr. DUDLEY S. REYNOLDS called attention to the occasional development of horny growths in the tonsils, in the posterior wall of the pharynx and on the base of the tongue. He recited the case of a woman, who for a long time attended his clinic at the Hospital College of Medicine, and in whose throat there were a large number of filiform bodies resembling hair. They were about one sixteenth of an inch in diameter, three fourths of an inch long, of symmetric growth, cylindric in form, with sharp-pointed extremities. They presented a dark muddy brownish color. They were removed with great difficulty, and when subjected to microscopic examination, turned out to be veritable horns, having all the characteristics of ordinary horny tissue. These growths resisted the action of caustics, the patient having been the rounds of other clinics for several years. She had a harassing cough. Dr. Reynolds found it very difficult to pull out these growths with the forceps. By seizing a number of them with serrated forceps, and cutting out the matrix with scissors, the growths were exterminated in sections, the second operation being delayed until cicatrization had taken place in the area embraced by the first, and so on to the conclusion. While such cases are not very common, they occur sufficiently often in the course of his practice to deserve mention among the causes of extrapulmonary coughs. They are in no sense of the word like either the milk-tinted masses of fungus disease, nor by any possible mistake in diagnosis to be compared with the ordinary concretions found in the little pouches, or dilated sinuses of the tonsils.

Dr. SCHERER reported a case of horny growths occurring in his practice, which he relieved by cutting out the matrix with scissors.

Dr. A. W. BRAYTON complimented Dr. Reynolds on his description of the growths, but insisted that the disease which produced them is nothing more than a mycosis. Such cases he regards as of sufficiently common occurrence to be considered in the list of causes of extrapulmonary coughs. He referred to an able essay on the subject by Dr. Klein of Indianapolis, presented to the Marion County Medical Society. Dr. Brayton remarked that, although the disease is a distinct mycosis, the action of strong acids is not sufficient to dissolve the growths. He does not doubt that many of them are really horny in formation and believes that the actual cautery is often the best agent for removing them.

Dr. PFINGST thought the massing of the pavement epithelium and the hair like appearance of the growths resulted from the tenacious adherence of the flattened cells.

Dr. CHARLES P. COOK had observed a peculiar cough, and a morbid sensibility of the throats of beer-drinkers, in some of whom milk-white bodies were present in the tonsils.

Dr. BARNHILL thinks the beer-drinker almost always exhibits varicose veins at the base of the tongue. He finds them also in neurotic and anemic women, about the period of the menopause. He has, in some cases, been obliged to puncture the varices to give relief to the distressing cough. Varicose veins in the space between the tongue and the epiglottis are most annoying.

Dr. SYMON P. SCHERER read a paper on

HEART MURMURS.

He thinks the habitual use of digitalis by physicians who do not regard the methods of physical investigation of conditions of the heart, and who divide heart murmurs into two general classes, often leads to grave consequences. The tabular location of normal heart sounds affords the only reliable means of comparison, either in deviation of position with reference to the character of the murmur, or the relations these bear to the systolic and diastolic movement. The comparison of both location and character of murmur in diastole or systole with synchronous pulsations of the carotid, afford in many cases the only means of diagnosis. If weak left ventricle with mitral

insufficiency, can be made out, digitalis may be used. Where muscular tonics, however, are required, strophanthus and strychnin are the most reliable agents. In some cases of aortic stenosis, with hypertrophy of the left ventricle and mitral insufficiency, the tincture of aconite, cautiously administered until the apex beat against the chest wall is reduced to a point of relief, great good may be accomplished. In this state of affairs digitalis does harm. In mitral stenosis, digitalis is indicated. In all atonic cases, strophanthus and strychnin; where venous stasis is present, salines and mercury should follow or accompany the use of strophanthus. The prolonged use of strophanthus shows no tendency to cumulative effects. The tincture in five to eight minims doses gives the most uniform results.

Dr. THOMAS EASTMAN of Indianapolis believes that great care and precision of method in diagnosis is essential in the treatment of the various forms of cardiac disease. He would like to emphasize his preference for the tincture of nuxvomica or the extract, in all cases where strychnin is indicated. He considers that all other alkaloids of the nuxvomica of greater value, are sacrificed by the substitution of strychnin. As a matter of preference he regards the tincture of nuxvomica as superior to all other preparations.

Dr. J. GARLAND SHERRILL has seen bad results from the prolonged use of digitalis, which he considers of great power for good or evil. He has known arteritis follow its use.

Dr. WM. V. MORGAN of Indianapolis considers that painstaking care in diagnosis will alone enable the practitioner to exercise sound judgment in the choice of remedial agencies. He reported a case of tuberculous cystitis, with hydronephrosis, which caused hypertrophy of the heart. If the cause can be removed, the compensating dilation of the heart should arouse no anxiety in the search for cardiac remedies.

Dr. G. W. BURTON of Mitchell does not think errors of diagnosis easily avoided. In his experience of forty years' practice he has occasionally found it impossible to make an entirely satisfactory diagnosis. He has no confidence in any tincture of digitalis, in fact he questions the value of any preparation, excepting the infusion alone. He has found the tincture of strophanthus an important though powerful and, therefore, dangerous agent. He has known it to do mischief in the hands of inexperienced practitioners. If all the difficulties in diagnosis could be mastered, then he would say cardiac lesions might be treated upon principles entirely satisfactory and rational.

In concluding the discussion, Dr. Scherer called attention to the aggravated dangers of cardiac medication in all forms of hypertrophy complicated with renal disease. As to the question of the best preparation of digitalis, he thinks most practitioners now prefer digitalin. In the choice of preparations of strophanthus he regards the tincture made by Parke, Davis & Co. as the most reliable and, therefore, the best preparation. He does not think the dose should exceed 5 minims to begin with. He thinks the profession in general is inclined to underestimate the value of aconite for diminishing tumultuous and rapid heart action.

Dr. DUDLEY S. REYNOLDS of Louisville introduced the subject of

CHOROIDITIS IN CHILDREN.

He maintains that many cases are overlooked in prescribing glasses for the correction of optic defects, and that disastrous results often follow. He contends that choroiditis in children is to be regarded as a manifestation of blood taint, or of that character of defective tissue growth found in mixed races. He is persuaded that very few mulattoes may be found entirely free from choroidal disease. From his limited opportunities of observation, he has reached the conclusion that those persons of mixed blood, of African paternity, with predominating Caucasian blood on the maternal side, never escape choroidal or retinal disease. Dr. Reynolds thinks the axial choroiditis of the aged, like that of infants, may arise from the imprudent exposure of the eyes to prolonged brilliant illumination. The disseminate choroiditis coming on at any period in life, he regards as distinctly characteristic of syphilis. He does not think it is often seen in cases of acquired syphilis, although he does think it sometimes appears late in life in acquired cases. He urges the necessity of having the eyes of every child carefully examined with the ophthalmoscope before permitting it to engage in the duties of school life.

Dr. ULRICH H. HON of Bloomington expressed great satisfaction with some of the conclusions of the essayist. He recited instances occurring in his own observation where the eyes of school children had been permanently impaired, and in some cases practically lost after the adjustment of glasses by itinerant opticians. He has known many cases where subsequent examination by expert ophthalmic practitioners disclosed irremediable disease of the choroid and retina. He is satisfied

that the importance of the matter would justify the expense and trouble incident to a thorough examination of the eyes of all children before going to school.

Dr. J. F. BARNHILL of Indianapolis deprecates the too common practice of permitting opticians to adjust glasses, without ever stopping to consider the conditions of the structures within.

Dr. EDMUND D. LAUGHLIN of Orleans, feels that something out to be done to prevent the practice of traveling opticians, often armed with certificates from prominent physicians, adjusting glasses to the eyes of every one who has sufficient money to pay for them. It is clearly the duty of the medical profession to aid both in devising adequate laws for the prevention of such criminal practice, and the enforcement of such laws as we already have. Until some united action on the part of the regular profession is taken, we shall be obliged to continuously witness the disastrous results of allowing itinerant opticians to tinker with the eyes of innocent children, and unsuspecting parents.

Dr. U. H. HON related the case of a modest, upright young man who had spent several months at some kind of school in Chicago, which issued a diploma or certificate of qualification, and which the young man used as an advertising circular to obtain patients. At first he seemed to think himself able to accomplish great good in supplying glasses to people who appeared to need them. Frequent disasters following his efforts finally discouraged him, and acting upon the advice of Dr. Hon, he confessed to have discovered great mischief in some cases where he had at first thought himself justified in supplying glasses, and finally abandoned the practice and engaged in an honorable business occupation.

Dr. A. W. BRAYTON of Indianapolis felt the question raised by the essayist concerning the hereditary influence down the maternal line, constituted the most important feature of the essay. He hoped Dr. Reynolds would continue to prosecute his observations, as he felt sure much good, and perhaps some new light, would result from a continuation of these studies. Dr. Reynolds is not alone in these opinions.

Dr. REYNOLDS, in concluding the discussion, referred to a case in the person of one of the servants at the West Baden Hotel. The patient's mother had but a trace of African blood. His grandmother on his father's side was reputed to be a white woman, while his father was quite black. The patient has extensive diffuse central choroiditis, with perception of light only in one eye, and just sufficient sight in the other to enable him to go about alone. He counts fingers at ten inches only.

Prof. WM. V. MORGAN of Indianapolis, read a paper on

INGUINAL HERNIA.

He regards all the injection methods of treatment with great disfavor. He thinks they should be opposed with unrelenting energy, as they serve but to complicate matters and greatly hinder any treatment that may subsequently become necessary. Naturally all operative procedure should be such as are designed to make complete and secure closure of the abdominal rings through which the hernia passes. He thinks in old hernias no attempt at radical operative procedure should be made until after the protruding intestine has been returned to the abdominal cavity, and remained there sufficiently long to establish tolerance of the reduction, after which two methods of dealing with the sac may be considered, with such modifications as good judgment and individual experience may suggest. Kocher's method has, for its chief feature, a small incision through the aponeurosis over the internal ring, using the finger as a guide, then passing a pair of artery forceps through the opening, and bringing out at the external ring the sac, which is drawn upward and twisted, so as to lie in a furrow outside the aponeurosis, in the direction of the inguinal canal, where it is securely sutured through the fibers of the aponeurosis, external oblique muscle, and the underlying fibers of the external oblique and transversalis, through the hernial sac, and into Poupart's ligament. The sutures bring together the anterior pillars of the external ring to which the sac is fastened. If the sac is very long, that portion which extends below the external ring is cut away. The Czerny method, in addition to high ligation of the sac sutured to the anterior pillars of the external ring, may be extended to include an attachment to Poupart's ligament so as to stretch the peritoneum smoothly over the ring through which the hernia protruded. The difficulties in both this, and other methods, notably Halsted's, lies in the fact that all attempts at creating obstructions against the recurrence of the hernia, by producing thickened and elevated surfaces, create at the same time increased liability of a return of the hernia by protrusion through the depressions on each side of the artificial elevation. One of the menacing difficulties lies in the determination of the best disposition to make of the cord.

Whether it is better to transplant the testicle into the abdominal cavity by placing it within the abdominal walls, adopting Halsted's method of reforming the internal ring, bringing the transversalis fascia, and a few fibers of the transversalis muscle along with a strip from the conjoined tendon, to be stitched across the inner ring firmly to Poupart's ligament, or whether it is best to simply raise or lower the cord, are questions difficult to determine. In many cases it would be far better before operating to have the consent of the patient to the removal of the testicle on that side, and then if removal should not become necessary, no harm or delay would result in the procedure. He shares Marcy's preference for the kangaroo tendon. He considers the following points should be kept in mind both before, and at the time of operating: 1. Attention to surrounding the internal ring by an aponeurotic band. 2. Hooding the cord. 3. Suspension of the testicles. 4. Making the site of internal ring smooth by drawing the neck of the sac across it. With Kocher, he concludes the results to be obtained make it the duty of every physician to advise a radical operation in all cases of inguinal hernia, in which extraordinary size, incarceration or inflammation, or complicating disease of vital organs, or the weakness of extreme old age, do not contraindicate a resort to the knife.

Dr. THOS. EASTMAN of Indianapolis has used the shotted suture, and silver wire, besides many other materials, and would decidedly prefer the wire in all cases where it is possible to use it; the silver wire suture he thinks, is not as popular with surgeons as it should be. He thinks its antiseptic properties are not sufficiently appreciated and that its more general employment would tend greatly to allay the frequency of stitch abscess.

Dr. THOMAS EASTMAN of Indianapolis read a paper on

THE TECHNIQUE OF MINOR GYNECOLOGY.

In his opinion many of the graver conditions ultimately demanding abdominal section may be so modified, or entirely controlled by timely interference, and by proper regard for technique in the administration of palliative and preventive measures as to establish complete restoration to health. Small lacerations of the cervix, frequently regarded as utterly insignificant, lead finally to the development of cicatricial masses, imprisoning terminal nerves, and causing a great variety of reflex disturbances, sometimes leading to the development of carcinoma. Generally these lacerations are so small and insignificant as not to require suturing, but where fungoid excrescences or excessive irritability develops, the direct application of the mitigated stick of nitrate of silver may be safely, and very beneficially made. He has no doubt that the timely use of such agencies would prevent a very large proportion of those conditions which ultimately lead to hysterectomy. In recent cases of displacement of the uterus, carefully introduced tampons may be found valuable correctives. In most of the inflamed conditions of the uterus, the vaginal douche, properly employed, is capable of accomplishing great good; improperly employed, it is an instrument of evil. Three points seem necessary in the use of the douche: 1. The water should be heated to 120 or 125 degrees. 2. It should be projected directly against the cervix. 3. The quantity should never be less than one and one-half gallons. The Hildebrand douche is best because it enables one to retain for a long time the hot water of the douche in contact with the inflamed and irritable cervix. The same may be said of ovariitis. Sometimes, in the latter condition, the tampon and electricity should be used. The faradic current is the best form, although galvanism in some cases may be desired. Many of the diseases of the Fallopian tubes, and ovaries, as well as the uterus, may be arrested in their early stages, which, if neglected, ultimately lead to the necessity of abdominal section.

Dr. SIMON P. SCHERER thinks that it frequently happens that the physician himself does not give sufficiently definite instruction as to the mode of applying the treatment. He recited an instance where he had directed the patient to take an injection for the relief of obstinate constipation. He explained that the fluid to be used should be placed in a bowl, from which it should be conducted into the bowel. Returning he found that the patient had failed in his attempt to take the injection, because he had expected the fluid to flow from the bowl into the bowel through the tube. He reproached himself for not having shown the mechanism of the instrument to be used. It often happens intelligent patients, when ill, exhibit an utter incapacity to reason about such things.

Dr. WM. V. MORGAN entertains no doubt of the value of electricity; the induced current will certainly contract the uterus. Faradic currents with coarse wire will as certainly relieve pain. It should not be forgotten the positive pole of a galvanic battery is the caustic current. As to the value of rest in delay-

ing the development of malignant conditions there can be no question. It has often been observed that cancer of the stomach occurs, by preference, in that portion which secretes hydrochloric acid, and he has no doubt if the acid were present it would prevent the growth of malignant tumor cells.

Dr. JOHN F. BARNHILL does not see how the propping up of the inflamed organ is to be maintained without incurring the risk of adhesions to the contiguous parts and organs, and these may become sources of annoyance equally as great as those which have been pointed out as indicating the necessity for operative surgery.

Dr. EASTMAN concluded the discussion by relating a number of instances of successful palliative and preventive measures employed at the clinic of Professor Gusserow.

The report of the sanitary committee being called for, Dr. Edmund D. Laughlin of Orleans presented the following, which after some discussion was unanimously adopted:

WHEREAS, An effort is now being made to place before Congress a measure known as the Public Health Bill, formulated by a committee of the AMERICAN MEDICAL ASSOCIATION at its last annual meeting, and subsequently unanimously approved and indorsed by the American Public Health Association, at the twenty-fifth anniversary meeting, held at Philadelphia in October last; and, in view of the urgent need of such an act by the Congress of the United States, thereby creating an organic law by which the proper officers therein specified may have power to act; therefore, be it

Resolved by the Mitchell District Medical Society, that we do most heartily concur in the effort to secure the necessary legislation upon this subject, and that we will urge our several representatives in Congress to promote the passage of such an act at the earliest possible period.

Resolved, That the secretary be instructed to forward a copy of these resolutions to the representatives in Congress from the district embraced in the territory from which the Mitchell District Medical Society draws its membership.

(Signed) EDMUND D. LAUGHLIN, Chairman.

Blue of Louisville; "Horse-shoe Fistula," J. Rawson Pennington of Chicago; "Some Recent Observations in the Use of Diphtheria Antitoxin," Hugh A. Cowing of Muncie, Ind.

EVENING SESSION.

The Society met in the banquet hall, President Sherrill in the chair.

An address entitled, "We Do as We Must," by Dr. Elihu P. Easley of New Albany, based on a consideration of the development of the brain, and the influences of education and environment upon the character and habits of the individual, evincing much erudition, was well delivered. It was discussed by Dr. Wm. V. Morgan, Dr. A. W. Brayton and others. At the conclusion of the discussion, Dr. Wm. D. Pennington announced, on behalf of the Committee of Arrangements, the conclusion of the program, and the banquet was inaugurated by calling upon Dr. Dudley S. Reynolds to act as toast-master. Responses were numerous, and of the usually bright and humorous character. The principal speakers were J. Garland Sherrill, Wm. V. Morgan, Simon P. Scherer, A. W. Brayton, G. W. Burton and Chas. P. Cook.

On motion, a vote of thanks was tendered to the West Baden Springs Company for many courtesies, including a magnificent menu for the banquet, and to Dr. Wm. D. Pennington for his efficient services as chairman of the Committee of Arrangements.

The Society adjourned to meet at West Baden Springs, Ind., July 20, 21 and 22, 1898.

Chicago Academy of Medicine.

Regular Meeting, Dec. 10, 1897.

Dr. A. LAGORTO in the Chair.

Dr. C. S. BACON read a paper entitled

VOMITING OF PREGNANCY.

Various theories to explain vomitus gravidarum have been advanced. A large number are theories of reflex vomiting which assume a peripheral source of irritation in some part of the genital tract. One theory assumes a stretching of the uterine fibers and disturbance of the uterus by the growing egg. G. Hewitt believed that vomiting is due to displacement of the uterus. Others assume irritation or inflammation of the cervix with erosion of the *os externum*. Horowitz believes that inflammation of the parenchyma of the uterus is the cause of vomiting, a

view similar to that held by Veit who finds in endometritis a very important etiologic factor. Tuszkai assumes an irritation of the peritoneal coat of the uterus due to trophic disturbances following the growth of the uterus. No one of these theories can account for all cases of vomitus gravidarum and the beneficent results of treatment founded on these theories can often be explained in some other way than by admitting that such results prove the theory. The theory of Kaltenbach that hyperemesis gravidarum is due to hysteria can not explain all cases, for there are many cases in non-hysterical subjects, but there is no doubt that a psychopathic condition is a very important element in the causation of the disease. The theory of direct vomiting due solely to immediate irritation of the vomiting center by poisons circulating in the blood, or to nutritional changes caused by disturbance in the circulation in the medullary centers, can not be maintained, for reflex action can not be wholly ignored. Hence we must assume at the present time, as the only theory that will explain all the facts and make of vomitus gravidarum a single disease, one that takes account of the condition of the vomiting center and also of the sources of peripheral irritation. We must assume that in two-thirds of all cases of pregnancy there exists an increased irritability of the medullary center due wholly or in part to one or both of these two factors: 1. Nutritional changes resulting from circulatory disturbances. 2. Poisoning from toxic elements circulating in the blood. We must further assume that this abnormally irritable vomiting center is acted upon by afferent impulses sent from one or more of a variety of peripheral sources. Among the most important causes of reflex irritation are an incarcerated, retroflexed uterus, abnormal adhesions of the uterus, pathologic changes in the uterine wall resulting from endometritis, pelvic congestion, constipation, chronic gastritis, etc. To these sources of afferent impulses must be added the psychopathic or hysterical condition which is of especial importance in the more serious cases.

Much can be done to prevent the vomiting of pregnancy, especially the more serious forms, by hygienic management, which consists in caring for eating, bathing, clothing, exercise, sleep, etc., preventing constipation and especially securing a healthful mental condition of the patient.

The indications for treatment of hyperemesis gravidarum are to allay irritability of the nervous centers, combat the neuropathic condition, hysteria, and remove the sources of peripheral irritation. Since the irritability of the medullary centers is due to disturbances of the circulation, and to intoxication, the means for treating this condition are pointed out to us. For maintaining a normal circulation the horizontal position, stimulation of the cutaneous capillary circulation, use of stimulants and vasomotor regulators, and injection of artificial blood serum, are the measures which promise the most. For antagonizing the circulating toxins all measures which stimulate the renal and intestinal excretories are indicated. The most important of these is also the salt solution. If the psychopathic or hysterical state be a factor in the vomiting it must be combatted by proper management. As in the treatment of hysteria so here it may be necessary to isolate the patient under the care of an experienced nurse and use all mental and moral forces, including suggestion. At the same time all possible sources of peripheral irritation should be discovered and removed. The constipated bowels should be carefully emptied with enemata and massage; a gastric catarrh may be treated with lavage, a displaced uterus replaced and pelvic congestion corrected by ice-bags.

Under this plan of treatment most cases can be controlled that have not advanced to the last stages of starvation. In the extreme cases the subcutaneous injection of large quantities of normal saline solution is proposed because of its effect in improving the circulation, in the elimination of toxins through the clogged excretories, and supplying two important elements of food, water and chloride. A case is reported to illustrate the worth of this measure.

Induction of abortion is opposed at all stages. When it is a safe measure to employ it is unnecessary, and in extreme cases it adds greatly to the danger, rarely stops the vomiting and can be substituted by the artificial serum. Three fatal cases are reported where abortion was induced without stopping the vomiting and where the operation may have been a factor in the fatal issue.

DISCUSSION.

Dr. CHARLES E. PADDOCK—I believe the cases the Doctor has quoted are instances of hysteria and we can attribute the vomiting more to this condition than any other. In other words, I believe it is more a condition of the mind than it is of any pathologic state. My experience has been that at least 90 per cent. of these cases can be cured by a little suggestion. What I mean by suggestion is the treatment advanced by the

Doctor, viz., of putting the patient to bed in the horizontal position, with the assistance of a nurse. The application of nitrate of silver applied to the cervix may do some good; it may at least satisfy the patient. My treatment in these cases has always been along that line, and I find that I can stop the vomiting by such treatment. In some cases I have sent the patient to her mother, or to some relatives in the country, and I have not had a case where the emesis continued after such treatment. Nearly all of the cases I have had of vomiting of pregnancy, unless there was the existence of some pathologic condition, have been cured in a short time, if they were able to go to the places recommended by me. The other cases were pathologic. We may find an erosion of the cervix which can be treated. We may find a malposition of the uterus to be the cause. I have had cases from retroversion and retroflexion, and particularly in incarcerated cases. The treatment of these cases is plain; remove the cause and you remove the trouble. In many instances I believe they are neglected. If they are pathologic we should treat them as such, and remove the cause. I could cite several cases which I have had in my experience.

Dr. J. HOWARD SLAYTER—I have nothing further to add to what Dr. Bacon has said, except a word or two with reference to saline injections. In cases of hyperemesis gravidarum, when saline injections are necessary, we find the vitality is much lowered, and therefore these cases are especially liable to infection. In some of them we find a dropsical condition, or one analogous to it, present, and this further adds liability to infection. Again, by the use of saline injections one may, waterlog the part injected and produce an artificial dropsical condition which will be followed by increased tendency toward infection. There are cases of hyperemesis gravidarum that contra-indicate a hysterical origin, for if they were hysterical it seems to me it would be a strange thing to find a genuine organic neuritis present, although occasionally it does happen that organic disease is associated with or complicates one due to functional origin.

Dr. FENTON B. TURCK—The paper presented may be considered a fair résumé of our knowledge of the subject at the present time. But we had expected from Dr. Bacon's wide experience to have gained more information regarding his personal observations of the etiology of vomiting of pregnancy. If vomiting were the chief phenomenon found in so-called vomiting of pregnancy or hyperemesis gravidarum, then the theory of excitation of the vomiting center from the growing ovum may appear satisfactory, but the most prominent factor we have found is the vasomotor disturbance. Associated with the vasomotor disturbance we observe a great amount of congestion of the mesenteric vessels, accompanied with congestion of the vessels of the pelvis. The evidence of pelvic congestion may be noted as one of the early signs of diagnosis of pregnancy, and the symptoms of general vasomotor changes are soon observed. More work is demanded of the heart until an eccentric hypertrophy gradually takes place. We often find great disturbance in circulation, cold hands and feet, surface of the body cold, features drawn and blanched, lowered blood pressure, heart disturbance and sometimes syncope. The universal method of treatment is to place the patient in the prone position and the use of hot water internally, hot coffee, carbonic acid gas, as champagne, etc., subcutaneous injection of normal saline solution; these and all methods which directly or indirectly affect the vasomotor disturbance are most successful. These facts would indicate that the disturbance of the circulation is a most important factor. Where a vasomotor disturbance exists, especially of the abdominal vessels, the motor power of the stomach and intestines is interfered with and a high degree of irritability of the viscera results. If there is retention of material within the stomach and intestines from a lack of motor power, mucus accumulates, especially during the night, together with exfoliated epithelial cells, pharyngeal secretions and other products, such as toxins of bacterial origin, as well as toxins that are excreted into the stomach. These act as irritants sufficient to stimulate the so-called vomiting centers.

If there is a marked degree of vasomotor disturbance of the splanchnic area there will result an increased irritability of the stomach whereby the vomiting centers receive more impulses, or are more powerfully stimulated than normally, and we may consider that the vasomotor disturbance also increases the irritability of the nerve centers. Therefore, bromids may sometimes be indicated.

We also find, associated with these cases, a dilatation of the stomach or prolapsus of the organ, due to the fact that the women wearing close-fitting and heavy garments about the waist produce these well-known pathologic conditions, such as a pyloric displacement which permits an accumulation within the stomach and sometimes regurgitation from the duodenum and act as an irritant sufficient to produce vomiting.

The third point that I would call attention to associated with congestion of the pelvic viscera and congestion of the mesenteric vessels, is the hypersecretion of the stomach and the involvement of the intestines and colon. The conditions above enumerated, the vasomotor disturbances and the gastro-intestinal disorders, including the colon, are quite sufficient to account for the vomiting that we find in hyperemesis gravidarum. And while I would not object to the term "hysteric," as applied to some of these cases, yet we find these pathologic conditions either existing or coming on during pregnancy, and I would rather ascribe the symptoms to known conditions than attribute the cause to a "neurotic," "neurasthenic" or "hysteric" condition, as these terms throw no light upon the pathology nor give any rational indication for treatment.

In the treatment it is necessary for us to meet the indications, especially the vasomotor disturbances that are found, and this is accomplished by the various methods described in the paper.

I wish to add that hydrotherapeutic measures applied within the stomach are very beneficial in overcoming congestion. It is necessary to use sufficient heat to produce vasomotor stimulation, as in shock, and in many of these cases I have found hot water at 130 degrees F., with the "intra-gastric resuscitator" or a hot water bag introduced into the stomach, of great benefit. This has acted upon the vasomotor disturbance sufficiently to reduce the symptoms of vomiting. Then treatment should be directed to the stomach itself and the intestines. I would emphasize, more than Dr. Bacon has in his paper, the great importance of vasomotor changes that occur in this disease, recognizing them as one of the elements of great importance and which may be found later to be the fundamental pathologic condition found in vomiting of pregnancy.

Dr. GUSTAV FUETTERER—There are three points I would like to touch upon. The Doctor recommends massage for the constipation of pregnant women. Does he recommend this as a rule, and without any fear of producing early uterine contractions? I would like to know how soon after the first hypodermatic injection of saline solution the tetanic attack appeared. I would also like to state that I have used hypodermatic infusions of normal salt solution quite frequently in different conditions and, particularly in one case, I have been able to explain the demonstrated effect to a certain degree by a post-mortem examination. It was a case of dilatation of the bladder with chills and high fever. I made an infusion of two quarts of salt solution. The pulse became of much better quality and the heart's action improved considerably. The fever decreased and the patient improved in the next twenty-four hours very materially. Then the septic symptoms appeared again, and two days thereafter the patient died. A post-mortem examination was made, some small miliary abscesses in the kidneys found, and I believe that at the time the salt infusion was made infection of the kidneys and general infection had just commenced. In this case it seemed, to me at least, that the infection had been arrested for at least twenty-four or forty-eight hours and then progressed again. As to the replacing of salts and the benefit of introducing them into the system again, I have had some experience along this line with consumptives. I have used these infusions in quite a number of consumptive patients, with gratifying results. Beneficial results were undoubtedly observable even in extreme cases.

Dr. J. G. KIERNAN—There has been shown a little tendency to criticize Dr. Bacon for his position as to the neuropathic aspect of hyperemesis. Without quibbling about the intermixture of the terms neuropathia, hysteria and neurasthenia, etc., it seems to me, in a strict pathologic sense, not in the sense of gross lesions, neuropathy represents a distinct nosologic condition. If there ever was a condition in which from the standpoint suggested, the subject was illy discussed, so far as hyperemesis is concerned, it is the pregnant condition. It would seem that in popular and general medical opinion a woman must be ill and vomit during pregnancy. There is a psychologic principle underlying suggestion in the treatment of this condition. If the *must* idea was not so much inculcated as it is by popular suggestion in regard to "longings," hyperemesis would be less noted. Furthermore, the therapeutic index is a good one. There is hardly an agent in the *materia medica* which, when first given by some man of admitted authority, has not produced miraculous effects in pregnancy hyperemesis. As time advances the effects are less. Let any one, for example, read Simpson's use of cerium oxalate of about thirty years ago, and compare his enthusiasm over it with the modified notions there are today, and he will be very much struck with the fact that there is a big difference somewhere between the effects of cerium oxalate then and today, and the most probable explanation of this is along the lines of

suggestion. A good many factors of hysteria, pure and simple, enter into hyperemesis. There is many a case, before the complete development of hysteria, in which the patient suffers from hyperemesis. Watson, in his old work on "Practice," mentions fairly typical cases of this kind. In hysteria, in neurasthenia and in neuropathic subjects occurs a condition liable to produce hyperemesis from slight causes of suggestion. Furthermore, it is well known that the mental state of the pregnant woman is peculiarly liable to suggestion.

To discussion of the question whether pregnancy be or be not a physiologic state, a great deal of time might be devoted, but there is not time to discuss that phase of the subject this evening. It does not resemble physiologic states. There are pain and other factors attending it. There are a good many morbid phenomena attending it as well. There is no denying the statement that the hysteric side of the pregnant woman is abnormal. As these women are liable to suggestion, the training should begin early. One person's training would begin with getting rid of the notion that vomiting was a necessary concomitant of the pregnant state.

Dr. TURCK spoke of pathologic conditions in these case cases, and his remarks reminded me a good deal of the old pathology of the insane. I can remember the time when physicians used to find lesions in the intestines and elsewhere to account for insanity. Nowadays these are known to be secondary, and not primary conditions. Take the class of women who are given to tying a string around themselves and crowding the viscera down in the pelvis, and abnormal intestinal states that may or may not develop these conditions will result. The fact is that while these abnormal states of displacement among a certain class of women are very common, cases of hyperemesis are rather infrequent.

With regard to the use of saline injections, the fact that under the old theory of their use a number of conditions treated successfully tends to justify their use. There is no doubt that in the conditions of collapse after cholera and allied conditions salines do have an effect.

I agree with Dr. Slayter that in an individual who is waterlogged or run down, there exist certain conditions which predispose to infection.

Dr. WILLIAM CUTHBERTSON—I wish to congratulate Dr. Bacon on the excellent paper he has read tonight, and more especially on the treatment of hyperemesis gravidarum by the hypodermatic use of saline injections. I do not think emesis gravidarum is due to any one cause, and more especially am I inclined to that opinion when I read the numerous remedies that have been suggested for the cure of this affection. Giles of London says he has found that primiparae who have had dysmenorrhea prior to pregnancy, are more especially liable to emesis gravidarum in the early months of pregnancy, and where emesis gravidarum occurs in the later months of pregnancy it is due to hydrops amni, to twin pregnancy, or to the large size of the child. He also cites cases where retroflexion of the uterus has produced emesis gravidarum, which condition has disappeared on the artificial correction of that state. Also, where emesis gravidarum has occurred in retroflexions of the uterus, that it disappeared when pregnancy has lifted the uterus out of the pelvic cavity. I think E. P. Davis mentions a case of hyperemesis gravidarum that terminated fatally, and at the post-mortem examination it was found that a cyst of the cervix had in all probability produced the condition. I must take issue with Dr. Bacon, however, when he condemns unqualifiedly the production of artificial abortion in the treatment of this disease. I think that where it is resorted to sufficiently early it no doubt saves a great many patients. About six years ago I had a case of hyperemesis gravidarum occurring in an extremely neurotic patient. She had also a retroflexion of the uterus, the uterus being bound down in the pelvis by adhesions. Shortly after the occurrence of pregnancy, vomiting began, which soon progressed to such a state as to endanger the life of the patient. After consultation, the induction of abortion was decided on and was accomplished by the introduction of a bougie, and almost immediately after the abortion the vomiting was much less, and finally within a week it ceased altogether.

Another case I would like to relate happened in my practice about twelve years ago. The patient was 35 years of age, became nauseated soon after conception occurred, and vomiting progressed to a dangerous state. After putting the patient to bed and using all the means then in vogue for correction of the trouble, the patient went from bad to worse. After a consultation, the induction of abortion was decided on, and was brought about by the use of a bougie. About forty eight hours after the introduction of the bougie the patient passed a fetus. Pregnancy had then advanced to about the second month. This happened in my practice in the country and I did not get

to the patient until some time after she had passed the fetus, but after the fetus was expelled the vomiting ceased. I thought, in all probability, the placenta had been expelled also, but had been lost sight of. The vomiting ceased for two or three days, and then it began again. I was called and found that she had passed a second fetus, and still no afterbirth. There was no hemorrhage, no elevation of temperature, so I thought the uterus was empty. There was a cessation of vomiting for forty-eight hours when it again recurred. At the end of this time the patient passed a third fetus, and on this occasion the afterbirth came. The vomiting ceased after the third fetus was expelled, and the patient went on to recovery.

I am a great believer in the hypodermatic injection of normal salt solution. In several cases of septic conditions, one case of mine, due to sepsis after emptying the uterus for eclampsia, the hypodermatic injection of normal salt solution reduced the temperature from 104 to about 100 degrees. The patient rallied considerably; there was a more free excretion of urine from the kidneys, but convulsions again set in and the patient died in a state of coma. In a number of cases of surgical shock I have used hypodermatic injections of normal salt solution with beneficial effects in almost every case.

Dr. G. FRANK LYDSTON—I believe Dr. Paddock was correct in stating that in his opinion hyperemesis gravidarum is not consistent with perfect health in a pregnant woman. Dr. Kiernan raised the question as to whether pregnancy was ever a normal condition. Probably not in a civilized woman; rarely at least in the eyes of the obstetric expert. The most salient point that struck me in the discussion was that psychopathy was supposed to be the explanation of the condition in the majority of cases. The element of suggestion, as applied to the cure of such cases is a little far-fetched. In the first place, I believe the report of every serious case of the kind under consideration should be associated with a very careful study of the urine and is incomplete without it. With our modern knowledge of the effects of toxemia dependent upon various toxins, it is not scientific to discuss a subject of this kind without a careful analysis of all possible sources of toxemia, the kidneys constituting the most probable source in cases of this kind. It is the fashion, however, to regard the kidney as being of little importance, providing the urine does not show a solid deposit on boiling, or on the application of nitric acid, or if it is not filled with all kinds of casts and epithelium. Possibly Sir Andrew Clark builded better than he knew, when he spoke of renal inadequacy, a condition in which the kidney may show no organic disease on chemic or microscopic examination of the urine, and yet does its duty so inefficiently that toxemia results. Operations upon the genito-urinary tract sometimes produce fatal results, through disturbances of the nervous system, and may possibly bring about serious results from organic change in the kidney, without any previous evidence of serious renal change. Reflex irritation of uterine origin may do the same thing. It would seem logical to infer that in some cases toxemia resulting from defective bowel elimination bears an important relation to the etiology of hyperemesis gravidarum. It is certainly worthy of thought, and without having made any experiments or observations on this point, I think it would be more logical than the view that these conditions are always of psychopathic origin.

Going back again to the kidney, the effect of irritations of the genito-urinary tract in both male and female, inhibiting the function of the kidney without necessarily the pre-existence of actual renal disease produced reflexly by the irritation, is a point that must be seriously considered. I believe that the principal obstacle to a proper classification has been the almost universal acceptance of the simple view that in all instances the disturbance is due to reflex irritation of uterine origin. The first thing the practitioner does is to look for some source of irritation in the vicinity of the uterus; the next thing he does is to apply something to the cervix, or go through some performance, psychic in its effect, we have heard tonight ostensibly for the purpose of relieving the source of reflex irritation. Cases of hyperemesis gravidarum are too important to attribute to one cause alone. I have no doubt that psychopathy enters largely into the causation in some instances, involving the question of hysteria, but I do not believe it covers them all. A latent neuropathic condition might reasonably be expected to develop and become active as a consequence of pregnancy in certain women. Another class of cases probably would be assigned to renal insufficiency without actual renal disease; another to actual kidney disease. Very likely the renal condition would be regarded by some practitioners as simply a coincidence and its source attributed to reflex uterine irritation instead of the condition being ascribed to its true source, actual renal disease, or toxemia possibly originating in defective bowel

elimination. That pelvic disease is responsible for a certain proportion of cases is evidenced by the cases reported by Dr. Cuthbertson and Dr. Paddock, in which reposition of the retroverted uterus relieved the violent and prolonged vomiting. I agree with Dr. Cuthbertson that abortion is to be considered under certain circumstances. I have seen cases in which it seemed to be indicated.

With regard to the treatment recommended by Dr. Bacon for its suggestive effect: taking it for granted that we have toxemia from renal inadequacy or other sources, or admitting that we have toxemia from actual renal disease, is it not possible that the saline injections relieve the irritation of the nervous system by their diuretic and diluent effect rather by modification of the circulation alone? I will grant that much for his method of treatment, but I will grant very little for the cases cited in substantiation of its claims. He cited two cases in evidence, one not his own recovered; the other died of infection and rendered further observation impossible. This patient was infected in two different ways with sepsis and tetanus.

Dr. BACON (closing the discussion)—In relation to the remarks of Dr. Lydston, I will say that I have given some attention to the renal functions in obstetric diseases, and I believe that the history of the growth of obstetrics is very intimately connected with the growth of our knowledge of kidney diseases. We have had various theories of eclampsia, and there was a time when it seemed only necessary to discover deficient elimination of urea to know positively the cause of eclampsia. When that theory was overthrown we began injecting animals with the urine of eclamptic women, and found eclamptic urine less poisonous than normal urine, and in that way determined that eclampsia is due to the retention in the blood of poisons which should be excreted in the urine. But these experiments have not led to the determination of the cause of eclampsia. I have made some inquiries of one of the physiologic chemists in this city to determine the possibility of making a series of experiments which might be of some real permanent value in determining the rôle played by the xanthin bodies in the pathologic condition of pregnancy. It is already too late to attempt to make the presence of acetone in the urine the key for the explanation of all pathologic conditions of pregnancy, as was done by obstetricians three or four years ago. Now we wish to find out the xanthin bodies. I was assured that it was absolutely impossible at present to obtain any definite information on that subject, and that any observations of the urine made for that purpose are quite worthless. The errors are too great. We talk about determining the elimination of urea by the Doremus test as if that was an exact method, when the slightest consideration will show that our results must be from 10 to 35 per cent. wrong. The time has not arrived to explain the vomiting of pregnancy by examination of urine. Any classification at present has to be based on the facts that are known. The talk about renal disease being the basis of scientific classification of hyperemesis gravidarum is useless. I expressly stated in the paper that I do not believe that hysteria is the only cause of hyperemesis. There are many cases of hyperemesis gravidarum where it is not the cause. But there are many cases where it is an important element as is shown by the curative effects of suggestion. A case described by Chazan is a good example of the value of suggestion in the treatment of these diseases. He was called to a serious case of hyperemesis. The patient had decreased in weight nearly half. She was in a desperate condition. It was thought necessary to perform an abortion, it being quite generally agreed that nothing else could be done, and he succeeded in controlling the patient simply by stating in a positive manner to her that she could control herself by the exercise of her will if she would only do so. She said to him it was quite impossible for her to do it. Then he mentioned to her the grave dangers of abortion, and finally succeeded, by the use of her will, in preventing the vomiting, so that in a week she had perfect control over her disease.

Such a case as this, and there are hundreds of them scattered through the literature, cured suddenly by the use of suggestion and by treatment along that line, shows the importance of the method of this treatment as well as the influence of hysteria in the causation of the disease.

I had expected considerable opposition to my views in regard to the induction of abortion. We do have severe cases which we are not called to see in time, and these are the ones where abortion is to be considered as one of the means that must be employed. The dangers are great indeed. A person in that condition is in great danger of loss of blood and shock. She is in grave danger of infection, and the results given in the literature of the subject do not show that abortion is entitled to consideration, even in the severe cases, and those who advocate it do not recommend it in severe cases.

Dr. LYDSTON—Do you believe these cases are curable if they are seen early?

Dr. BACON—I believe if these cases were seen early there would be no fatal cases, unless there is disease associated with hyperemesis, such as cancer of the pylorus or some disease of that kind.

A word or two in regard to the induction of abortion in the cases cited by Dr. Cuthbertson. If abortion is performed it should not be done by a bougie, but by rapid dilatation and clearing of the uterus, because it is important that the case should terminate as soon as possible, and secondly, by the rapid method there is much less danger of infection. In regard to Dr. Slayter's suggestion as to the danger of infection from hypodermatic injections of normal salt solution I admit that there is danger from injections in dropsical conditions, but these conditions are not present here; on the contrary water is absorbed rapidly by the dry tissues.

In reply to the questions of Dr. Fütterer I will say that tetanus developed five or six days after injection in the first case. It is probable that the tetanus infection was from the injection, although no bacilli were found in the tissues, but of course that does not prove very much. How the infection occurred I can not say. The injection of fluid was not made by myself. In regard to massage I will add that I believe it to be a valuable measure in treating constipation in pregnancy, and not dangerous if carefully employed.

I am quite in accord with Dr. Turck as to the importance of vascular changes in pregnancy, but we do not know enough about the subject to make them the sole basis of a classification. I was very much interested in Dr. Kiernan's additions to the pathologic signification of hysteria.

SELECTIONS.

The Management of Patients Before and After Laparotomy.—Dr. Frederick Holme Wiggin, in a paper read before the Hartford Medical Society and the New York Medico-Surgical Society, January, 1898, considered the management of patients before and after laparotomy as follows: In the early days of the decade now drawing to a close, it was generally believed that abdominal operations could not be safely performed outside of hospitals especially constructed for such work; but it is now known that although personal effort and responsibility are increased, it is perfectly safe to do such operations in ordinary houses. It is, therefore, not improbable that in the near future many of these patients will prefer to be operated on at home, and this means that the general practitioner will have a more important part to play in the management of these cases than has been customary in the past. Where circumstances will permit, one week should be devoted to preparing the patient for the operation. This time can be profitably spent in accustoming the patient to the new environment, in examining the heart and lungs, and the condition of the secretory and excretory organs and in thoroughly evacuating the bowel. Early in the week several small doses of calomel and soda should be given daily, for three days, and followed each morning by a saline. On each of the three succeeding mornings a large enema should be administered, consisting of three or four quarts of saline solution. In order that these large enemata shall be properly given the physician should superintend this part of the work, taking care to see that a fountain syringe is used, that it is not more than three feet above the patient, that the solution has a temperature of 100 degrees F., and that the flow is checked from time to time as the patient complains of colic or of intestinal distention. Six hours before the operation the rectum should be given a final washing out with the same solution. The diet during this week should be light and easily digestible, and the patient should be encouraged to drink freely of liquids and to rest as much as possible. Every day, a hot bath (110 degrees F.) should be given for ten minutes, and in the daily ablutions special attention should be paid to the navel and pubic region. The nervous system may be quieted by administering, on alternate nights, a mild hypnotic, such as a combination of sulfonal and chlo-

ralamid, and arranging its administration so that a dose is given on the last night before the operation. The skin of the abdomen is prepared for the surgeon by applying a soap poultice over the proposed site of the incision for two hours, and then substituting a compress moistened with weak bichlorid solution. If the patient is a woman, the time selected for the operation should, if possible, be a few days after the cessation of the menstrual flow, and the vagina should be thoroughly douched, first with a solution of boric acid, and afterward, with a 0.5 per cent. formalin solution, or a 1 to 4000 solution of bichlorid. It is better to operate in the early morning than in the afternoon. If the former has been selected, the patient should be given a peptonized milk punch at eleven o'clock the previous evening. The administration of an ounce of liquid peptonoids about two hours before taking the anesthetic stimulates the heart and diminishes the subsequent nausea and vomiting. If the operation is to be done in the afternoon, the peptonized milk punch may be given in the early morning, and the peptonoids at 11 A. M. The patient's body and limbs should be properly protected with clothing during the operation. The furniture of the room should be removed and the windows left open for two or three hours. Then, the wood-work should be wiped off with bichlorid solution, 1 to 1000, and the floor liberally sprinkled with the same solution. The operating table should be about 20 inches wide and thirty high. The following articles should be provided, and, after cleansing and washing with bichlorid solution, should be placed in the room: Several small tables or stands, a few wooden-bottomed chairs, several pitchers and meat platters, four or five basins and a fish-kettle for the instruments. In addition, there should be several gallons of both hot and cold water, sterilized by boiling, and at least a dozen towels sterilized by steaming. For emergency cases it is safer to cover the floor with a sheet wet with bichlorid solution than to stir up the dust of the room by more elaborate preparations.

The anesthetic should be administered before bringing the patient into the operating-room, and if ether is to be employed, it is better to give, subcutaneously, half an hour before, $\frac{1}{8}$ grain morphia and $\frac{1}{100}$ grain of atropia. A closed ether inhaler allows of the easy and rapid induction of anesthesia and the maintenance of this state with a minimum of the anesthetic. The skin is finally prepared for the operation by a scrubbing with hot water and tincture of green soap, followed by irrigation with sterilized water, ether and alcohol. If the patient be a woman, it should be made an invariable rule to irrigate the vagina and swab it out with gauze. The author strongly favors making the incision through the right or left rectus muscle, instead of through the linea alba. He also believes that leaving a considerable quantity of hot saline solution in the general peritoneal cavity, after irrigation, acts as a stimulant and at same time tends to prevent the formation of intestinal adhesions. In closing the abdominal wound the deep sutures should be placed at least one inch apart, and loosely tied. The edges of the skin may be accurately adjusted by a buried suture of silkworm gut. If, during the operation, the pulse increases twenty or thirty beats, a subcutaneous injection of $\frac{1}{12}$ grain of strychnia and $\frac{1}{100}$ grain of nitroglycerin should be administered, and repeated as required. If in spite of this treatment the pulse exceeds 150, one or two pints of warm saline solution should be at once introduced into the median cephalic vein. The patient should be put to bed with warm blankets and bottles, and soon after consciousness has been restored, should receive one dose of $\frac{1}{100}$ grain of atropia and $\frac{1}{8}$ grain of morphia. It is not necessary to keep the patient in one position for the first few days. For the first twelve or eighteen hours nothing should be given by mouth but small quantities of warm water. If there is much gastric irritation, it may be relieved by the external application of chloroform to the epigastrium. After this period, a drachm of liquid peptonoids may be given

every twenty minutes for four doses, and then small quantities of peptonized milk may be cautiously added, gradually increasing the quantity, and lengthening the interval. Once in twenty-four hours an interval of six hours should be allowed in order to rest the stomach. If there is much intestinal distention, this can be relieved by the introduction of a rectal tube or the nozzle of a syringe, or by massage along the course of the colon. Usually no cathartic need be administered until the third or fourth day, and then small doses of calomel and soda should be given, followed by two or more Seidlitz powders. If, as is usually the case, the temperature is normal by the evening of the fourth day, the patient may be allowed to rapidly resume ordinary diet. The dressings should be changed on the fifth day, and if the sutures are cutting through, they should be removed and the wound supported with strips of adhesive plaster. The complications which may be met with occur in the following order: Concealed hemorrhage, peritonitis, intestinal paresis, intestinal obstruction and stitch abscesses. As soon as concealed hemorrhage is diagnosticated, an intra-venous saline injection should be administered, but it is useless to operate unless the patient shows a reasonable response to stimulants. The onset of peritonitis is usually announced by a steady increase in the frequency of the pulse, and this should be the signal for the prompt evacuation of the bowel by calomel and salines, and by enemata of glycerin and water, or of a saturated solution of sulphate of magnesia. When there is intestinal paresis the stomach should be washed out and salines freely administered. As soon as intestinal obstruction is recognized, the abdomen should be re-opened and the constriction relieved. Stitch abscesses usually announce themselves by the fourth or fifth day. In estimating the patient's condition, the facial expression is of the greatest value.

Keratosis Follicularis (White); "Porcupine Disease."—Dr. J. C. White in the *Boston Medical and Surgical Journal*, November 11, has given a clinical demonstration of this new affection. Both Darier of Paris and Dr. White in 1889 recorded a case, the former naming his as being a *psorospermose folliculaire végétante*. Dr. White used the term *keratosis follicularis*. The disease appears to be a simple hyperkeratosis, a modification of the process of cornification consisting in heaping up of modified cells in the mouths of the follicles. The clinical appearances were very various, consisting in the beginning of small horny papules, closely resembling the keratosis of lichen pilaris of the arm. From these the process extended into larger semiglobular elevations, hard and becoming somewhat discolored. These were all seated at the mouths of the follicles. By confluence there grew large horny concretions here and there, one-third to one-half inch in height and of about the same diameter. The disease at its highest point of development consisted of conical projecting horns resembling miniature cutaneous horns. In that case the whole surface of the body was largely covered and in certain parts the process was enormously developed. "The case in Paris, which I subsequently saw at the International Congress, had not advanced to this degree, but Darier and other French observers asserted that it was a case of psorospermosis and that the peculiar cells found in the tissues were psorosperms, or coccidia, and the name psorospermosis has remained from that time to this. Since then other cases have been observed, but only a very few, in other parts of the world. I do not doubt it was in existence a long time before and it is my opinion that so-called 'porcupine men' (*ichthyosis hystrix*) were cases of this disease. When I returned from Paris the first patient I saw on entering the clinic was this patient and she presented the same affection. By one who had seen the disease it was immediately recognized by this peculiar appearance of the face. The disease has not advanced very greatly since that time. The whole forehead is occupied by a mass of horny papular growths.

Behind her ear the process is much more fully developed. On other parts in the pubic region this process is still more highly developed. There is a little on the wrists. It extends down on the chest in front and in the rear about the same distance. There is a little scattered eruption on the arms and legs. The very peculiar bodies which are found in every one of these papules, large round cells, are not, it has now come to be believed, animal parasites, but are peculiarly modified epithelial cells. It is not a coccidial disease and even Darier has given up that opinion. Although the French name remains, *keratosis follicularis* is the proper name, because it is a descriptive title and not misleading. We have a case here which is of medium grade, and my first case was this young woman's father. That does not indicate that it is a contagious disease, because this girl was less than a year old when separated from her father and never saw him afterward, nor does it show necessarily a hereditary tendency to this affection, because it is only in one or two other instances that it has affected more than one member of a family."

PRACTICAL NOTES.

Treatment of Gastro-Intestinal Catarrh.—Liebreich recommends for the cases in which the diarrhea can not be treated with opiates: Tincture of calumba and tincture of cascarrilla, each 10 grams. Twenty drops four or five times a day.—*Semaine Méd.*, January 12.

Tetanus and Trismus Treated with Behring's Serum.—Two more cases successfully treated with Behring's serum are reported in the *Munch. Med. Woch.*, No. 46, 1897. Mortality in tetanus usually varies between 50 and 80 per cent. The mortality in the cases treated with Behring's serum, as recorded to date in literature, is 41.8 per cent., which should encourage its further use.

Test for Aceton in the Urine.—Mallat first distills the urine to a quarter of its original volume, and then applies the principle that a solution of iodine will precipitate iodoform in contact with an alkaline solution of aceton. The amount of aceton is determined by the amount of iodoform precipitated. *Nouv. Remèdes*, January 8.

Alumol-Iodin Treatment of Metrorrhagia.—Grammatikati's method of treating catarrhal endometritis with intra-uterine injections of equal parts of tincture of iodine and a 5 per cent. alcoholic solution of alumol, has been applied by Orlov, with great success, to the obstinate metrorrhagia of the critical period. He reports three cases remarkably improved by two or three injections, and practically cured by ten or twelve.—*Semaine Méd.*, January 12.

Air-Tight Drainage.—Ikawitz supplements the ordinary Kocher fenestrated drain tube with another closed tube, with a projecting rim at the junction. The rim fits in with a suture; the drained fluids are collected in the bottle tube; the dressings kept dry, and if the subcutaneous tissue alone is to be drained, the bottle tube with its rim is sufficient without the Kocher part.—*Cbl. f. Chir.*, Dec. 31, 1897.

The Hemostatic Action of Hyposulphite of Lime is announced by Silvestri, who has arrested with it hemorrhage of all kinds, from that accompanying round ulcers to postpartum and endometritic hemorrhage. He administers an average of eight grams a day divided into six powders, and attributes its action to increased coagulability of the blood. *Semaine Méd.*, January 12.

Treatment of Psoriasis with Arsenious Acid.—Herxheimer confirms his previous announcement in regard to the efficacy of this treatment. He reports ten completely cured; six so improved that they were satisfied with a partial cure, and seven still under treatment. He commences with 0.001 acid. arsen-

icosum, and increases by the same amount each day until the dose reaches 15 mg. which he continues until complete cure, usually requiring forty-eight days. He states that secondary effects were slight, and that if the affection should recur, he believes that a partial course of treatment would promptly abort it.—*Cbl. f. Chir.*, Dec. 31, 1897.

Auscultation of the Mouth.—Professor Galvagni calls attention to the valuable information to be derived by auscultation of the mouth in regard to incipient tuberculosis, etc. The râles are reflected from the bucco pharyngeal cavity as from a sounding-board. He also notes a peculiar jerky glottic sound, not in the inspiration, but commencing in the pause, attaining its height about the middle of expiration, diminishing and vanishing completely at the commencement of the inspiration. It coincides with the rhythm of the pulse, and has been noticed in several tuberculous patients, and in one case of gastralgia of uterine origin—*Gazzetta degli Osp. e delle Clin.*, December 5.

Iodoform Injections in Tuberculous Lymph Glands.—Hammer-schlag has been remarkably successful with intraglandular injections even in the large celled hyperplastic lymph glands on tuberculous subjects, which usually are sent to the surgeon. In the case of well-to do patients he precedes the injections with the general anti-tubercular treatment, climate, baths, etc. After local anesthesia he injects one to two centimeters of the 5 to 10 per cent. iodoform-glycerin emulsion, first on one side and a week later on the other. He states that the result in his six cases was remarkably rapid and satisfactory, the tumors subsiding until not a trace could be seen above the skin and no scars left. In another case he found the results equally fine although the injections were made in the periphery of the gland, and he suggests that others with larger material at their command might experiment whether periglandular injections may not be as efficacious as the intraglandular.—*Deutsche Med. Woch.*, December 23.

Prophylaxis of Nephritis in Scarlet Fever.—Professor Alfaro of Buenos Ayres prevents altogether this dangerous complication of scarlet fever by observing the following precautions: 1. Keep the diuresis abundant with a strict milk diet, plenty of drinks, and cold hydrotherapy in severe cases. 2. Avoid the elimination by the kidneys of any irritating substances either from medication or from the food (avoiding phenol, salicylic acid, antipyrin, acetanilid, etc.). 3. Keep the functions of the skin as active as possible by general friction with fatty substances and tepid bath during desquamation. 4. Keep the mouth, nose and pharynx aseptic with frequent mild antiseptic applications to prevent the introduction of the streptococcus into the general circulation. 5. Avoid sudden or continued exposure to cold air. 6. Use no antipyretics or antiseptics that could possibly affect the kidneys injuriously by elimination or absorption.—*Anales del Circ. méd. Argentino*, October 15.

Tuberculosis of the Ganglia of the Neck.—Cervical scrofulous adenitis is no longer considered a morbid entity, but merely that the scrofulous predisposition induces cellular hyperplasia in ordinary infections more readily. This hyperplasia persists and forms a favorable soil for the development of tuberculosis, which may remain localized a long while. The infection occurs almost always by way of the lymphatics, with caries of the teeth, the tonsils, adenoid vegetations, etc., for the entering point. Tuberculous adenitis develops almost inevitably into the fistulous form; absorption or calcification are extremely rare. There is a form of adenitis which presents the characteristics of tuberculosis, but proves to be non-bacillary. In the suppurated form there may be secondary infection, but pus collections are frequently observed, especially in the adult, which develop rapidly and yet only contain the Koch bacillus. This form of tuberculosis very rarely extends toward the mediastinum; owing to the arrangement of the lymphatics the ten-

dency is toward the axilla. The best treatment is thorough extirpation, a simple operation in non-suppurated cases. Interstitial injections should be reserved for the cases in which an operation is rejected, or counterindicated by the general condition.—*R. Petit, Gaz. Méd. de Liège*, December 23.

Tincture of Myrrh in Diphtheria.—Dr. Ströll, writing in the *Allgemeine Medicinische Central-Zeitung*, very strongly recommends tincture of myrrh in diphtheria. The mixture he uses is composed of tincture of myrrh 4 parts, glycerin 8 parts, and distilled water to 200 parts. This is given very frequently, every hour or even every half hour in the daytime and every two hours at night, infants up to the age of two taking a large teaspoonful (75 minims), older children double that quantity and adults three times as much. This is continued until the membrane has nearly disappeared, when the doses are only given every two hours. After all the membrane has gone the treatment is continued for a couple of days, the interval between the doses being increased to three hours. This is with the view of preventing any recurrence. Usually the fever and lassitude disappear in twenty four hours, so that a child may frequently be found within that time sitting up in bed playing. He says that there does not seem to be any need for local treatment; in the case of older children and adults a gargle containing 0.5 per cent. of resorcin may be employed every hour or oftener in the daytime, and where it is desired the tonsils may be painted every hour with the tincture of myrrh undiluted. Where the larynx is involved Dr. Ströll prescribes the myrrh and glycerin mixture, in an inhaler or spray to be used every half hour. By the employment of this method Dr. Ströll states that he has only lost one case out of eighty and he has collected reports from several other practitioners in various parts of the world who have treated altogether 182 cases with 22 deaths. No mention, however, is made in his own or in the other cases of bacteriologic verification of the diagnoses. The *rationale* of the efficacy of myrrh is supposed by Dr. Ströll to be that this drug increases the phagocytic elements in the tonsils.

Protargol, a New Disinfectant.—The prolific factory of the Bayers at Elberfeld presents a new candidate for disinfectant honors, a compound of silver and protein. This substance was discovered by Dr. Eichengrün, the chemist to the above factory, and is termed "protargol." Dr. Benario of Frankfort has now examined its action and publishes his results in the *Deutsche Medicinische Wochenschrift*. He states that it is an energetic bactericide, a 1 per cent. solution destroying the bacteria of anthrax and enteric fever, as well as pneumococcus, bacterium coli, staphylococcus pyogenes aureus, etc. In experiments made with rats it was found that injections of 2 c.c., of a 1 per cent. solution caused necrosis at the place of the injection, but were not fatal to the animal. An injection of 1 c.c. of a 10 per cent. solution produced an infiltration and total necrosis of the skin, the animal dying in a fortnight. A 20 per cent. solution dropped on the conjunctiva of rabbits produced an increased secretion of the lacrymal glands; an application of pure protargol caused abundant swelling of the eye and the surrounding tissue. But within five days the normal state reappeared, the cornea being clear as before. Injection of a 1 per cent. solution into the urethra caused a slight smarting. The purulent secretion nearly disappeared within a week, and in a fortnight gonococci were no longer discoverable. Professor Neisser of Breslau, who also tried the remedy, stated that he had never before had so good, sure and prompt results in gonorrhea. In surgical practice it was used for the dressing of wounds in about 150 cases. In phlegmonous inflammation, dressings moistened with a 5 per cent. solution were applied; in recent wounds the substance was used in the form of powder. In various ulcerations it was employed as an ointment, while in tonsillitis a 5 per cent. solution applied to the inflamed tonsils proved useful.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, FEBRUARY 12, 1898.

THE TYPHOID FEVER DEATH RATE.

The death rate from typhoid fever in this country during the census year 1890, was 46.27 per 100,000 persons, but as this is recognized as under-stating the facts from the necessarily imperfect character of the returns, a better idea of the prevalence of this fever may be obtained from the death rate, 53.25 of certain urban populations in which the records were considered to be accurate. The death rate from typhoid fever in England was in that year only 17.9 per 100,000, and that this was not an exceptional year is shown by the last published report of the Registrar-General, which shows only 17.5. Moreover in every 100,000 of our population we recorded about 20 deaths from malarial fevers, a considerable proportion of which was certainly due to the infection of typhoid fever, while the English have no analogous additions to their recorded typhoid rate. These statistics are startling when we consider that far from being an unknown and mysterious epidemic influence, the cause of this fever has been recognized and many of its modes of propagation have been discovered. Thousands die annually of typhoid fever in the United States without disturbing the general equanimity, because the disease is indigenous and the people are accustomed to its ravages; but were an exotic disease causing a similar death rate to be introduced, no effort would be considered too great to effect its suppression. Money would be spent freely to stamp out the pestilence; but money spent freely in giving the people of every city, town and village a pure water for domestic use, would free the country in a great measure from this indigenous scourge. In 1872 Massachusetts led

the way in an effort to preserve the purity of her rivers and public water supplies. Other States, as Illinois, Minnesota, New York and New Hampshire followed in her lead, but sanitary progress is slow. For several sessions a bill has been before Congress to prevent the contamination of rivers and other natural water sources in which the citizens of more than one State are interested, but no action has been taken.

Now, however, that attention has been directed to the condition of the Potomac supply of Washington, D. C., it is to be hoped that something may be done. On January 10 last, the Secretary of War was requested to furnish the United States Senate any information in the possession of the War Department in relation to the filtration of this water-supply, together with any suggestions on the subject by the Surgeon-General of the army and the officer in charge of the Washington aqueduct. Surgeon-General STERNBERG reports that as compared with other cities in this country and abroad, the sanitary condition of Washington as judged by the typhoid fever mortality is far from being creditable, and that the relatively low death rate of 53 per 100,000 of the past year (the annual average of the past twenty-two years having been 64) was probably due to the replacement of a number of box privies by running closets, improved drainage of premises and a closer supervision of the milk-supply. As to the Potomac water he states that sanitarians in all parts of the world look upon the typhoid fever mortality of a city as the best index of its sanitary condition. It has been repeatedly demonstrated that the introduction of a pure water-supply or the filtration of a sewage polluted water, together with the introduction of a well devised system of sewers, has a notable effect in diminishing the mortality from this disease. Observations made by bacteriologists in Washington show in the Potomac water the almost constant presence of bacteria, indicating contamination by fecal matters of man or the lower animals. Fecal contamination of a stream, the water of which is used for drinking purposes, is always an indication of possible danger. General STERNBERG considers the construction of filter beds to be the most reliable and practical method of improving the quality of the Potomac supply, but suggests that before entering on an undertaking of such importance and cost, it would be judicious for Congress to appoint a commission to investigate the subject, with authority to visit Europe for the purpose of witnessing the practical workings of filtering basins now in use, and to estimate the cost of a basin suitable for the purification of the Washington supply.

An investigation of this character under Congressional auspices would have an influence which would extend beyond the banks of the Potomac to other streams and sources of supply. It would arouse local authorities to an understanding of the conditions

under which typhoid fever prevails, and would suggest the urgency of procuring that which every community should have, a plentiful supply of pure water.

All this shows the need for a Department of Health to act on behalf of the Government in this and other matters pertaining to the public health in the territories and the District of Columbia; to advise the health authorities of the various States and co-ordinate their efforts to reduce the mortality from preventable diseases.

NEW FACTS IN REGARD TO VITALITY.

It is not very long since the current physiologic theories of vitality practically assumed that we knew all about it, or if we did not we soon should, as it was only a special manifestation of physical and chemical laws. Our knowledge of the subject has not contracted any since then, but we have learned facts that cause us to better appreciate its limits, to be a little less presumptuous in our ignorance, and to recognize that in the phenomena of life we have evidence of an agency not correlated with the ordinary forces of nature and not controlled by but controlling or guiding the ordinary recognized laws of matter.

A recently published paper (*Nature*, December 9) by HORACE T. BROWN and F. ESCOMBE, recapitulates a number of facts already made known, but neglected, and adds some striking ones that are new and due to the investigations of these authors. It is well known that seeds retain their vitality and germinative power for long, and according to popular belief almost indefinite periods. The condition of the protoplasm in seeds in their inert state has been to some extent a matter of dispute, and while some authorities have held to a theory of continued but minimal vital activity, a sort of intramolecular respiration, others have maintained that metabolism is completely suppressed, and that there is for the time an absolute loss of all the power of internal adjustment to internal relations, which according to HERBERT SPENCER is the essential characteristic of living substances. To test this ROMANES made a series of experiments which were in their way remarkable; he subjected seeds to a number of tests, placing them in high vacua, of only one-millionth of an atmosphere for periods of fifteen hours. Others still were subjected to the actions of various gases, oxygen, hydrogen, nitrogen, carbon monoxid, carbon dioxid, hydrogen sulphid, aqueous vapor and the vapors of ether and chloroform. Neither the high vacua nor the subsequent exposures for long periods to the above-named gases had much if any effect upon the germinative power of the seeds, though in some of the above conditions ordinary respiration by gas exchange must have been practically abolished. There remained however a possibility of some chemical interaction; it is therefore impossible to say that all

metabolic activity was altogether suspended. These experiments though interesting and suggestive are not quite conclusive.

In 1881 WARTMANN subjected seeds to a temperature of -110 Centigrade (-166 F.) without effect on their vitality, and three years later DECANDOLLE and PICTET reported similar experiments, using temperatures of -78 to -120 C. In 1893 PICTET claimed to have exposed seeds to nearly -200 C. without effect, and concluded that, as all chemical action is annihilated at -100 C. (-148 F.) vitality must be a special law of nature, like gravitation, and not under the other known laws.

These prior investigations rather detract from the originality of Messrs. BROWN and ESCOMBE's experiments, but they are not offered as the first of the kind, and are so detailed and complete as to be of especial value and interest. By the slow evaporation of liquified air they succeeded in submitting a number of seeds of common plants, including among them representatives of the Leguminosæ, the Liliacæ, the Graminacæ, etc., air-dried and thus still containing 10 or 12 per cent. of moisture, to a temperature of 183 to 192 C. below zero (-297 to -313 F.) for one hundred and ten consecutive hours. Then they were carefully thawed, the process lasting about fifty hours, and their germinative power was found to be unimpaired; there was no appreciable difference in this respect between the seeds thus treated and the others used in the control experiments.

This result is the more striking since these were all highly organized species of plants, while some of the lower organizations succumb to less extreme temperatures. In 1892, for example, DEWAR and MCKENDRICK found that a temperature of -110 C. for one hour sterilized putrescent substances. This would indicate that certain saprophytic bacteria in their active state were unable to endure low temperatures. What their potential vitality might be in a germinal or non-active condition is perhaps another matter. DECANDOLLE, from his experiments, concluded that protoplasm must be, while still vital, inert in these low temperatures and compared the condition to that of an explosive mixture which is a storage mass of energy though quiescent. BROWN and ESCOMBE also come to the conclusion that there is no conceivable possibility of any metabolic activity existing in the seeds under the conditions in which they placed them, and that we will therefore have to modify our conclusions and definitions of life or vitality. HERBERT SPENCER's definition already alluded to, which has been perhaps as much a favorite as any—that it is a continuous adjustment of external to internal relations—must be given up as insufficient; it is a definition of vital activity rather than one of life itself. We may have to fall back on BICHAT's circular definition, that life is the sum of the influences, whatever they may be, that resist death, as

an expression of our ignorance of the real nature of vitality.

There is still another point raised by the English experimenters. In 1871, Sir WILLIAM THOMSON (now better known as Lord KELVIN) made the suggestion that the origin of life on our planet might be due to germs transported from other worlds by meteoric bodies. This was hardly considered seriously at the time, the conditions in space being considered such as to preclude its probability. These recent experiments show that it can not be the temperature of interstellar space that makes the hypothesis an improbable one and give a sort of plausibility to the suggestion. There are of course other factors to be considered, but these recent developments add a new interest to speculation, while they deepen rather than clear up the mystery of life.

PROTECTION FOR THE RED CROSS.

Senate Bill 1913, "To protect the insignia and the name of the Red Cross" passed the Senate Jan. 6, 1898 and was referred to the Committee on the Judiciary by the House of Representatives on the following day. This seems at first sight like a praiseworthy bill entitled to the support of every humane and patriotic legislator, but when we come to scan it and the arguments in its behalf we find that there are in existence two RED CROSSES, one of which is official and has asked for no protection, while the other in petitioning for protection speaks as if speaking for both and as if authorized to do so. The first is the Red Cross, the hospital flag and the badge of hospital corps neutrality of all the nations that have accepted the articles of the Geneva treaty of 1864. The 7th article of this treaty provides that hospitals and ambulances shall carry in addition to the flag of their nation a distinctive and uniform flag having a red cross on a white ground; and that their staff shall wear an arm badge of the same colors, the delivery of the brassard for the arm to be made by the military authorities. The 8th article provides that the details concerned in carrying the other articles into effect shall be left to the Commanders of armies. This is the only Red Cross which our Government recognized in accepting the treaty of Geneva, as it is the only Red Cross mentioned in the articles.

The sympathies and energies of those who were instrumental in bringing about this treaty led them to suggest the formation in each country of an association to gather supplies for the wounded and even to take the field in aid of the Army Medical Department in case of need, these national associations to be united into an International Association for systematic co-operation in great wars. Accordingly this International Association was formed, and it *assumed* the Red Cross of the treaty as its flag and insignia,

although no article of the treaty authorized the assumption, but on the contrary articles 7 and 8 indicate the military authority or War Office as the only power competent to authorize the wearing of the Red Cross neutrality brassard or the hoisting of the official hospital flag. Nevertheless the United States branch of this International Association, incorporated under the laws of the District of Columbia as the American National Red Cross asks Congress to make it unlawful for any person or association of persons to wear or display the sign of the Red Cross without permission from the American National Red Cross, for the purpose of collecting, soliciting or receiving money or material or who shall by the use of said symbol or name of the American National Red Cross do or attempt to do similar work to that of the American National Red Cross, without permission from that organization.

We have four prominent objections to the passage of this bill. 1. As a general principle no restraint should be imposed on the charity or humanity of individuals, states or nations. 2. The bill fails to distinguish between the Red Cross of the treaty and the same cross assumed as the insignia of a local organization. Indeed from the ingenious manner in which both are mixed up in the preamble of the bill, it would require a reference to the highest court to determine whether on its passage the U. S. Army and State troops could continue to wear their badge of neutralization, unless with permission of the American National Red Cross. Moreover as there is officially only one Red Cross, that of the Geneva treaty, can Congress overlook the provisions of the treaty and authorize an Association to distribute its specific and sacred badge at its pleasure? 3. The bill fails to protect the Red Cross as there is nothing in it to prevent anyone from placing Red Cross brands of tobacco or whisky, etc., on the market. 4. The scope of the bill is more extensive than its title. It is a bill to extend and exemplify the powers of an association, incorporated under the laws of the District of Columbia, by recognizing it as a federal institution, the only one through which voluntary aid could reach the sick or wounded of the Army, because the only one by whom or through whom could be worn a red cross indistinguishable in form, color, size and position from the Red Cross of the Geneva treaty. If the citizens of Massachusetts, Louisiana, Illinois, or any other State desired in time of war to come to the aid of the Medical Department of the Army by collecting and forwarding supplies, or by outfitting a volunteer corps for field or hospital service, they could under existing conditions obtain safety for their supplies and neutrality for their personnel from the military authority competent to grant the use of the Red Cross under the articles of the Geneva treaty, but under the terms of this bill they could do nothing without first

touching their cap to the then chief of the American National Red Cross.

If any bill to protect the Red Cross is passed by the Congress of the United States, it should be one to protect the Red Cross of the Geneva treaty and to prevent its use in any way except under the terms of articles 7 and 8 of the said treaty. Miss CLARA BARTON, the President of the American National Red Cross, stands high in the esteem of the U. S. Military Surgeons for her efforts to secure the formal acceptance of the Geneva treaty by the U. S. Government. and in times of calamity her name becomes a household word throughout the country. The aid given under her superintendence at various times, as during the forest fires in Michigan in 1881, the earthquake in South Carolina in 1886, the Johnstown inundation of 1889 and the tidal wave of 1893 shows that the work of the American National Red Cross can be efficiently performed without such legislation as will compell all aid and assistance contributed by U. S. citizens to be registered under its stamp and seal.

THE HUNT MEMORIAL.

The dedication of the Hunt Memorial Society Hall at Hartford, Conn., was the occasion of more than local interest. Dr. HUNT had been a leading physician for nearly half a century, and his family, to commemorate his name, offered the local medical society a building for a library, museum, laboratory and lecture room. The society purchased the ground and a thirty thousand dollar building has been erected for this purpose. The dedication was marked by a notable address from President GILLMAN of Johns Hopkins University of Baltimore. The building is especially adapted for social and scientific work. Large cosy parlors and sitting rooms, with a kitchen and dining room, after the fashion of a modern club are provided. Other rooms are fitted for laboratory and chemic research and the foundation of a large library has already begun. Rooms for research, writing and consultation of books and periodicals are large and well arranged. One large lecture hall and several smaller rooms for society meetings are provided, and altogether this building is most admirably adapted as a home and resort for men. One of the peculiarities which sounds strangely is the provision for a free dispensary. A set of rooms has been fixed up for the work of a dispensary under the care and control of the society. In a city of seventy thousand inhabitants with two hospitals and two dispensaries, to open another for free charity, or to combine those in operation, seems out of harmony with the sentiment of the best medical experience of the present. Fortunately the dispensary is only a project and not yet organized, and probably will never come into practical existence. Outside of great medical centers this is

the first building for this special purpose which has been erected. In almost any town of any size, secret and other societies, with clubs of every description, have houses and special buildings as permanent homes, while medical societies are practically houseless. There are probably not more than a dozen buildings owned and occupied by medical societies in the country. Physicians often urge the endowment of hospitals and dispensaries, when they should ask for a society home, which would be a greater charity.

One of the great wants of the day is a closer union of medical men in their work and practical every-day life. In large towns and cities a medical club house with library, laboratory and social rooms are indispensable for this purpose. The Hunt Memorial Hall in Hartford is a model of what should be erected in every large town and city of the land. It is understood that further endowments will be made to this memorial building so that the expense of sustaining this house will be nominal to all its members. The time has evidently come for a change in the organization of free dispensaries and hospitals, and the rush of physicians to give free services, both pauperizing themselves and their patrons. If the same energy displayed in this direction was turned to provide society homes and libraries, an immense advance would be noticeable in the practice of medicine. Every society of thirty or forty members should have a medical club house, with every facility for scientific and social recreation. Young men of limited means could find here libraries and opportunities for study invaluable to them. The great number of periodicals could be gathered and kept on file and books from all sources would accumulate, and valuable libraries now lost could be kept together on the death of the owner. The periodicals and books together with everything pertaining to medical progress would accumulate here, making it a center of increasing interest to all medical men. Not the least of these privileges would be the social part, and the lecture room. If men of other vocations can build expensive club and society houses, and receive permanent good from such associations, why should physicians not do the same? It would seem that medical society homes were indispensable for all practitioners, even more so than homes for men in trade or other professions. The example of the Hartford society in their Hunt memorial home, should be followed by every medical society in towns and cities where the profession can gather without much loss of time and effort.

NOTIFICATION OF CONTAGIOUS DISEASES.

"It shall be the duty of every physician called to attend a person sick or suspected to be sick with cholera, yellow fever, smallpox, diphtheria, scarlet fever, measles, whooping cough, typhoid fever, typhus

fever and tuberculosis of respiratory organs, within twelve hours thereafter to report the name and residence of such person to the board of health or its proper officer within whose jurisdiction such person is found." etc.

Such is the substance of a resolution recently passed by the Department of Health of Cincinnati, and it is the expressed intention of the efficient health officer that the resolution shall be carried out as far as possible. This move on the part of the department is no doubt a beneficial one to the general public, but we should stop for a moment and consider what part the doctor in attendance is to play in this extended line of prophylaxis. He must fill out the printed postal cards and send them to the department, or otherwise notify it, under penalty of a fine or imprisonment for failing so to do, and the remuneration he receives is his inward satisfaction and relief in having complied with the rules laid down by the political heads of the municipal government. He receives no compensation whatever and whose fault is it but his own? Does anyone ever see a lawyer doing any of this charity work for the good of the general public? Was a politician ever known to fill any office in a health department and gather these reports and not be paid for doing so? Is not the doctor, if fortunate enough to have property, taxed the same as other people, does he not have to pay rent and in several cities register or procure a license to practice, which in no instance is made a present to him by the State or city, and has it not been decided by some courts that man (even a physician) is entitled to compensation for the work he does or the services he renders, and hence why should he not be compensated for his share of the enforcement of this regulation? This may be regarded by some as a too mercenary or business-like view of the practice of medicine, but in these times when the clientelage of the physician almost invariably pay everyone else before they pay him, when the courts in many instances deny the physician his just dues, when the public expects the doctor to contribute the best years of his life (made short by the many hardships and exposures he is compelled to endure) to the care and treatment of many cases of charity who are unable to compensate him in any degree, or to the army of dead-beats who resort to every means to avoid paying their bills, it is time that the doctor took a little more business-like view of his calling. He should value the years he has spent in the most laborious efforts to perfect himself in his art, the thousands of dollars he has expended in education, library, instruments, etc., and then profit by the examples of thousands of practitioners who have lived long and noble lives in caring for the sick, and at the close of their life of hardship, exposure, anxiety, study and privation, have been unable to save enough to leave their widow or family in circumstances little short of penury.

There can be no valid reason why a moderate fee should not be allowed for such reports when made by a physician. The rich and affluent need not demand or receive it, if they do not so choose, but there are physicians to whom even this stipend would be welcome and it certainly is only just that the worker should receive his wage.

CORRESPONDENCE.

Appendicitis: Rejoinder to Dr. Carstens.

RICHMOND, IND., Jan. 23, 1898.

To the Editor:—If Dr. Carstens will read carefully, he will see that I am not opposing operative methods, as I said in two of these cases I had been called to operate and found one case dying, and a second so much improved that I declined to operate; and in two other cases, not included in the eight reported, they refused operation, and a third not included recovered. Hence it is unfair to represent me as being opposed to operation (I am not). But in a careful study of the disease and from reports of surgeons I am still of opinion that many cases under judicious treatment would recover and avoid the knife. I have, as I reported, made postmortem examinations whenever possible, to study the nature and progress of the disease, and am not wholly a novice in operation. . . . My experience teaches me to conserve human life on both lines, viz., by operation and no operation. Hence it is a question of enlightened judgment and not by the *ipse dixit* of him who may be lacking in the careful study of cases. He says: "The article refutes itself." Now, if the Doctor had read carefully . . . that I was called to operate in two of the cases, he would not have said I was opposing operation and advising more conservative treatment. I do not claim that some of these cases were judiciously treated, or treated at all for this trouble, and that is a reason why they died. It does not change the facts in the case. The statement was made that "the ambitious who are inexperienced" operate when a patient is *convalescing* (which was not true in any of these cases), "but the experienced surgeon will postpone an operation and urge an operation in the interval." Then he goes on to say: "However, all experienced surgeons urge immediate operation upon every case, claiming that the mortality will not be more than 2 to 5 per cent." I answer: They do not, and Dr. Carstens is not authorized to represent the surgical profession so dogmatically, as I can show to be so from records coming from attainable sources and by accomplished surgeons who have been in the field perhaps longer than my reviewer. . . . As to recurrent attacks, it is not true in the cases recovered in this list so far; no case has had a recurrent attack and I am as well advised as to this fact as is Dr. Carstens, but I answer, that it is not true that recurrence occurs as often as appears in the statement: and especially when we remember that the troubles which occur in this region of the body have not been accurately diagnosed in the past, or even in the present day, and there is room for careful observation all along this line of diagnosis. Again, Dr. Carstens is at fault when he says: "If the eight cases had been promptly operated upon the (*first day*) seven at least would have recovered, and not been in danger of subsequent attacks." Now, the Doctor assumes that but one might have died, and furthermore he is at variance with all authority when he says operate on the first day of the disease. It will take the first day at least to be sure of your diagnosis. He evidences too great a confidence in his own methods of diagnosis and too vivid a confidence in what the knife can accomplish to justify me in believing he is a careful or methodic student of cases by a careful analysis and classification of symptoms in such cases;

and if I am correct in this conclusion, I am also correct in the conclusion that he is only proving, just what I have hinted at, that a more conservative study and treatment of these cases would save many lives which are not saved by the knife. One of these cases I reported, in which I was called to operate, proved that if he had been operated upon at any period of his recurrent attack, it would have been useless, as the changes produced in the tissues, revealed by postmortem, showed that no operation could have saved him.

Again, I refer Dr. Carstens to a controversy between Dr. Terry of Utica, N. Y. (in the *Medical Times*), and Dr. R. P. Morris of New York, also a warm advocate of the knife and quoted as an authority upon appendicitis.

The case is not settled by Dr. Carstens, nor by any one observer, in favor of the knife, no matter how strongly he states it, yet we believe it will come to be settled, as many other surgical questions are being settled, by a more careful diagnosis and a more careful, conservative treatment, which does not necessarily exclude the operative method, when safely or judiciously applied. My conviction is still, that when a larger number of cases with careful diagnosis and treatment, promptly begun, with a rigid rule of quiet in bed, the statistics will still be largely on the side of recovery by conservative treatment, and I would use this treatment, even with knife in hand, and would operate if I became satisfied I ought. And a man should have the courage of his convictions on either side in harmony with all facts known to exist bearing on the case. I do not here enter into any discussion of the pathology but adhere to my first position, that we are coming to the time when a more enlightened and conservative treatment will yet relegate the surgeon's knife in this and other abdominal troubles to the shelf. I have indubitable proof, in my own experience as compared with other surgeons, that the knife, which was supposed to be the only resort to save life, has failed and patients have recovered without it, and continue to live and enjoy good health.

Comments: *Obiter dicta* in practice are opinions expressed by those who think they know, on points which do not necessarily arise or exist in cases under consideration.

Dicta are to be regarded as of but little authority, on account of the manner or form in which they are presented, and are often given without much or sufficient reflection and without sufficient data. If, says Huston, "general *dicta* in cases turning on special circumstances are to be considered as establishing rule or law, nothing is yet settled, or can long be settled." It has also been said to be a great misfortune that *dicta* are cited (opinions) and then, when gone into print, are taken as absolute propositions. This may be the position our reviewer is in, and yet his *dictum* does not go. It was not supposed that a few cases would settle a rule of statistics, but only as going to make up a large number which guide to the truth.

The facts in the cases reported clearly show that the five cases which recovered were those who received a careful, discriminating treatment, not all by the writer, and those who were lost neither had judicious nor safe treatment, but refused the aid of surgery when offered them, and this puts an entirely different view than the one supplied by Dr. Carstens.

I am not alone among medical men who have grown old in experience who are taking the same view, that the *obiter dicta* of the present generation of younger surgeons does not yet settle questions, but that the statistics which will prove a rule of action to the surgeon are not yet complete and will not be till more cases and more time has been taken to determine them. I only expressed a personal judgment drawn from a large private and hospital experience which a large body of men in the profession now entertain, that the knife has been too handy an instrument, and we want a more careful and methodic study of cases before we rush in "where angels might fear to tread."

Thalamon, one of the younger men in medicine and surgery, has given us a masterly résumé of the subject and in it says, "and moreover, if we take all the forms of appendicitis as they come, without making any distinction, we know with certainty that in 90 per cent. the disease gets well without the aid of the surgeon, which shows that as far as the life of the patient is concerned the immediate progress is not so grave and that one may safely wait." Again, he says: "No precise time can be fixed for an early operation; the limit may vary from the third to the fifteenth day." Carstens says the first day, and there is but one case reported as being operated on in the first twenty-four hours, or first day. This case recovered, and yet how does anybody know that in the progress of the case recovery might not have occurred. I would be glad to know in how many cases which recover the operation was indispensable to save the life of the patient. Can any man answer? "The chances," says Thalamon, "for life offered by laparotomy are not very great and it is probable that the chances are *nil* after the fifth day." Here we must draw a clear distinction between the circumscribed and general peritonitis or hyperacute forms and those not so. The rule of Treves was "not to operate before the fifth day." The question recurs, when is the opportune time and who shall decide but the surgeon who has the case? Evidently Dr. Carstens is one of those who believes in immediate operation or early operation, and thus sets up a standard of his own. One thing now to be noticed is the statement that the operative measure is attended by 2 to 5 per cent. mortality, which is much larger than this. When facts are studied on both sides of the question, viz., statistics of operations and those of non-operative cases, they will show from 10 to 15 per cent. of recoveries after operation, while the results of carefully conducted treatment show a better result, which leads Thalamon to say, "that naturally there has been a reaction against this zeal for use of the knife." And to the apparently triumphant statistics of the American surgeons, physicians have replied by statistics more emphatic and decisive (49 to 51). Yet we are still to remember that statistics will not finally settle this question, but judgment, skill in diagnosis, effective control of patient and control of pain in each case, judicious use of remedies in control of inflammation, so-called peritoneal.

R. E. HAUGHTON, M.D.

Proportion of Physicians to Population.

SYKESVILLE, MD., Jan. 24, 1898.

To the Editor:—The statistics quoted in the *JOURNAL* of January 22 (p. 231) from "Hirschwald's Medical Directory" furnish a good refutation of the reckless statements so often made by careless writers in American medical journals concerning the great disproportion in the number of physicians to population in this and other countries. I have thought it might be of interest to give a comparative statement of the number of physicians to the population in a few of the large cities in the United States and in the German Empire. The figures for the former are taken from "Flint's Medical and Surgical Directory" for 1897 and the "New York World Almanac" for 1897 and 1898, and those for Germany from the work mentioned above. The statistics are as follows: United States: New York, 1 physician to 650 of population; Philadelphia, 1 physician to 661 of population; Chicago, 1 physician to 840 of population; Baltimore, 1 physician to 676 of population. German Empire: Berlin, 1 physician to 780 of population; Breslau, 1 physician to 864 of population; Munich, 1 physician to 798 of population; Frankfort, 1 physician to 795 of population. For the entire German Empire, 1 physician to 2143 of population. For the Kingdom of Prussia, 1 physician to 2181 of population. The population of New York is as estimated on Jan. 1, 1897; that of the other American cities as estimated

Jan. 1, 1898. The German statistics of population are said to be from the latest official census.

It is well known that in American registers of physicians there are many entries of persons who may have the degree of M.D., but who do not practice medicine. Others have the degree of Ph.D., and still others are called Doctor or "Doc" by courtesy. I have gone over the list purporting to give the names of physicians in Baltimore, and find that 4 per cent. have no right there. They are either Ph.D.'s or M.D.'s who have devoted themselves to other pursuits than the practice of medicine. By excluding this 4 per cent. of non-practicing doctors, I find that in Baltimore the proportion of physicians to population is 1 to 704, not very much in excess of the proportion in Berlin. The 4 per cent. eliminated does not include homeopaths, herb doctors, and all other quacks, nor those who have died within the year. I imagine the German statistics only give those who are legally entitled to practice.

There is another point to which I want to call attention. The belief is general in this country that in Germany, and especially in Prussia, no one is allowed to practice medicine without having passed the so-called "Staats-examen." Now, I have good reasons for doubting this, but it may be true. If true, there ought to be some way of finding out beyond question that it is so. Have all the 14,582 physicians practicing in Prussia, or the 2148 practicing in Berlin, passed the Staats-examen? Or, are there persons practicing medicine in Prussia or in Berlin, who have not passed this Staats-examen, which is constantly held up to us for our admiration and imitation? and if the answer to the last question is affirmative, as I believe it will be, where does the great superiority of the Prussian system come in? Very truly yours,

GEORGE H. ROHE, M.D.

A Genuine Department of Health versus Psychic Sanitary Measures; Which?

CHICAGO, Feb. 7, 1898.

To the Editor:—I was curious to learn the purport and meaning of the "Caffery Bill," pertaining to legislation for the hygienic welfare of the people of this county and, after reading the same as published in the JOURNAL (February 5, pages 330-331), I can say that I am utterly opposed to this substitute bill.

To my mind this substitute bill is not what the medical profession nor the great majority of the people of this country desire. It has very little semblance looking toward the establishment of a genuine department of health as a separate branch of our government, and I will venture the prophecy that the views of 90 per cent. of the members of the medical profession throughout the United States are not in accord with this proposed substitute bill which has been suggested to take the place of the bill that has been carefully prepared by the special committee of the AMERICAN MEDICAL ASSOCIATION and which was introduced into the Senate by Senator Spooner of Wisconsin on January 27 last, and is known as Senate Bill 3433.

There may be mugwump bacilli or psychic bacilli that science and sanitarians will have to contend with in the far distant future, but for the present generation at least, we are entitled to, and should be afforded the most ideal and thorough scientific department of health that it is possible to contemplate, exactly on the theory that when any person or any of our national legislators of either house of Congress, or within their domestic fireside are stricken with disease, they desire the best medical skill obtainable.

We are admonished that, presumably within a week or two, this substitute bill known as the Caffery bill will be introduced into the House, and our influence and work must necessarily, for some time at least, now be exerted with representatives in Congress. Shall this be done?

Before closing, I might with propriety propound this query also (which is not intended so much for the aggrandizement of our profession as some might be led to believe).

Would it not be well for the President's cabinet to be dignified by the acquisition of a scholarly and thoroughly scientific medical secretary exactly on the same principle as the presidential family is composed of gentlemen versed in diplomacy in matters of state, finance, the judiciary, the science and art of war, etc.

Let us have a department of health, therefore, as has frequently been outlined in the JOURNAL, on the same theory that if we want a spade, a spade will be provided for us and not a spatula, or if we ask for a stick of wood that a wooden toothpick will not be substituted.

Very sincerely yours,

LISTON H. MONTGOMERY, M.D.

Method of Examination of Urine.

OMAHA, NEB., Feb. 3, 1898.

To the Editor:—Apropos of the ingenious method for the detection of casts described by Drs. Haines and Skinner in the JOURNAL of January 29, it may be of interest to describe the method which has been in use in my laboratory for the past few months. I depend entirely on the centrifugal method and use only tubes containing at least 15 c.c. Both tubes are filled to the 15 c.c. mark with the freshest possible specimen of urine and centrifugalized at from 1800 to 2500 revolutions per minute for three minutes; then at least 10 c.c. are withdrawn from the tubes with a pipette, being careful not to shake; the tubes are again carefully filled with the pipette and again centrifugalized; this process is repeated ten or twelve times, so that in about half an hour we have the sediment in each tube from at least 115 c.c. urine, 230 c.c. in all. Then the bottom 3-5 c.c. of both tubes are placed in one tube and again centrifugalized. This method has been especially useful in the examination of urine for tubercle bacilli, where by spending a little more time we often use the sediment from 500 c.c. This method is rapid, thorough and avoids a tedious delay, as well as the necessity for any preserving agent. As a proof of this efficiency I may add that in over 200 examinations of which records are kept, a few casts have been noted in every instance, even in apparently healthy individuals.

Respectfully,

AUGUSTUS DETWILER, M.D.

X-Ray Dermatitis; Suit for Damages.

PADUCAH, KY., Feb. 2, 1898.

To the Editor:—In October, 1897, the undersigned was sued for malpractice in the sum of \$10,000 for subjecting a patient to the X-rays which produced a severe dermatitis, the plaintiff setting up the claim that the apparatus was carelessly used, and further that the means used was not yet sufficiently well understood as to warrant its use for the purpose of locating foreign bodies, etc. The suit was ably contested and fortunately was decided in my favor, the court holding that in this as in other cases the physician was bound to use ordinary skill and judgment, and placed the case upon the same footing as chloroform anesthesia.

Knowing that there were several suits of this character in the courts I thought perhaps it would be of some interest to report it, since I have as yet been unable to find that the subject has been previously passed upon by the courts.

Respectfully,

FRANK BOYD, M.D.

PUBLIC HEALTH.

Louisiana State Board of Health.—The *New Orleans Medical and Surgical Journal*, January, alludes to the fact that that Board of Health is temporarily dismantled, all the members who were in office during the recent outbreak of fever having

resigned. This step was taken on account of the demand of the daily press and various commercial bodies, representing the *vox populi*.

Direct Contagion of Typhoid Fever.—A striking instance is reported from Bucharest, where ninety-six cases of typhoid fever occurred in a crowded military school of 300 inmates, spreading directly from bed to bed. No local cause for the epidemic could be discovered, and it was traced to two pupils who had returned from an infected locality.—*Bull. de l'Acad. de Méd.*, December 21.

Malarial Fatalities on the Southeastern Coast of Africa, in Railroad Building.—Dr. Emil Holub, a South African scientist and explorer, speaking of the new Gazaland railway that traverses a part of the intensely malarial coast line, belonging to the "sphere of influence" of Portugal, says that that railway has earned a sad notoriety by reason of the great loss of life that has marked the course of its construction. During the past five years the contractors have contended with almost insuperable difficulties in procuring sufficient labor. More than seven hundred workmen have died from malarial fevers. Some of these were from Europe, but the majority were Asiatic natives. Out of 500 Afghans imported for this work, by way of India, 350 died in a short time. The divide between the shore line and the inner lofty tableland has been passed and the death-toll has been greatly reduced.

Death Rates of the Past and Present.—One of the events of the British Jubilee was the presentation of an address by the Lord Mayor and Sheriffs of London to the Queen on the subject of the sanitary improvements during her reign. The summary as ably condensed in an issue of the *New York Sun*, brings forth some startling facts. In Macaulay's comparison between the London mortality of 1844 and that of 1684, it appears that the death rate of 1685, not a sickly year, was between 43 and 44 per thousand, or one in every twenty-three. At the present moment the London death rate is 14.9 per thousand despite the enormous increase in the population. During the ten years from 1838 to 1847 the mean annual death rate for England and Wales was 22.16 per thousand while the ten years from 1881 to 1890 was 19.1 per thousand. This implies that 77,000 out of an estimated population of 29,000,000 were kept alive in each year of the latter period who would have died in each year of the former. All of which proves the value of mathematical precision in the calculation of life-values as affected by surroundings and the diffusion of intelligence.

New York State Board of Health.—Before the above named board Dr. George B. Fowler, on behalf of the Antitoxin Committee, has reported that the committee has notified the various manufacturers of antitoxin as to State supervision of its manufacture and sale in New York State. The manufacturers he said were in hearty sympathy with the board, and promised to aid it in the carrying out of the plan to have antitoxin tested before it was offered for sale. In the absence of reports on the subject from local bacteriologists the matter was adjourned for one month. The State Board will probably determine to have all the bacteriologic work done in the laboratory of the Health Department of New York City before the serums can be placed on sale as officially approved remedies. This is the plan pursued in Europe where every ounce of serum is inspected by duly authorized officials in the state laboratories. Dr. Herman M. Biggs, bacteriologist of that department is reported as saying that as a result of investigations he found several of the samples of serum submitted to him unfit for use owing to the occurrence of decomposition. Some of it was considerably below the standard strength.

The Latest in Regard to Beriberi.—A committee was sent from Holland to study the three epidemics of the diseases supposed to be beriberi at the Richmond Insane Asylum at Dublin, and

their report has just appeared in the *Nederlandsch Tijdschrift voor Geneeskunde* for December 11. While they are not too positive, as a disease may assume different characteristics in different countries, yet they do not consider the epidemic polyneuritis at Dublin identical with the beriberi of the Netherlands colonies. The localizations are different; the extreme relaxation of the articulations observed at Dublin, "dropped wrists and feet," is unknown in the East Indies, and other symptoms are quite different. *Janus* (Vol. ii, No. 1) contains the results of an investigation of the hundred indigenous prisons in Java (280,000 inmates), with a view to determining the influence of the food on the appearance of the disease. The results are striking. The principal article of food is rice; in some prisons it is used with the pericarp, in others completely shelled. Where it is completely shelled the proportion of cases of beriberi to the number of prisoners is 1 to 39; where the pericarp is eaten with it the proportion is 1 to 10,000; where a mixture of the two kinds is used the proportion is 1 to 416. Further statistics show the disappearance of the disease in institutions in which the unshelled rice has been substituted for the shelled. In Japan, he states that the rations for the army and navy now include a certain proportion of barley and bread instead of the previous exclusive rice rations and beriberi has almost entirely disappeared.

Experiments in Disinfection at the New York Harbor Quarantine.—Experiments with formaldehyde gas are in progress at the quarantine station at New York, the principal tests having been made with the micro-organisms of cholera, diphtheria and the plague, on board the new steamboat belonging to that office. Other tests were made in a room in the laboratory which had been especially supplied for the purpose with an apparatus for spraying liquefied ammonia all about the room, in order that the gas might be neutralized whenever it was necessary. In the account of his experiments, the Health officer, Dr. A. H. Doty, describes twenty-five separate tests, in each of which three or more varieties of germs were used. Some of the experiments were made in a room of moderate size, containing about 1,000 cubic feet of air space. Others were in an air-tight steel box containing about 115 cubic feet of air space. In the series of experiments made with the steel chamber, the disinfecting solution in amounts ranging from eight to ten ounces, was exposed for different periods of time. Into a woolen blanket, cultures of different germs were rubbed, and in fifteen tests in which the quantities as well as the periods of time were varied, only one culture of the germs showed any signs of growth subsequent to the exposure to the solution. That was the diphtheria germ. Tests were next tried *in vacuo* as that method offered less resistance to the penetration of the gas. For twelve hours he exposed a quart of the solution. He used the germs of the Indian plague, of diphtheria and of anthrax. Some were exposed on linen, some were wrapped in a blanket, and others wrapped in a newspaper. These lived under the exposure to the gas, while others inside an envelope between a single sheet of paper, and inside a towel, were killed by the gas in nearly every case. A greater degree of success was met in subsequent experiments, in which it was learned that the gas was given off more satisfactorily by the use of a solution of some neutral salt. The apparatus was set up in the disinfecting steamer, and after four hours' exposure, every germ of cholera, plague and diphtheria was killed. These results were obtained when the germs were inside as many as three sheets of paper and envelopes, and were closed as tightly as possible. Fully four hours were needed, however, to make the tests successful. The value of the new disinfectant will be appreciated most at our harbors as a means of disinfection against southern ports. Already the mail tests with formaldehyde have been highly successful, and it is efficacious, too, in the case of blankets, towels and newspapers. It is said to have no bad effect on animal life and can be used without detriment.

The Department of Public Health.—The State Board of Health, of Indiana, has issued the following special circular:

The following resolution was passed by the Indiana State Board of Health at its regular meeting December 17, 1897:

WHEREAS, An urgent necessity exists for a more extended supervision and control of contagious and infectious diseases, to prevent the introduction of said diseases into the United States and the spread from one State to another of the same; and

WHEREAS, A bill to establish a National Department of Public Health and define its duties has for the past ten years been under serious consideration by the AMERICAN MEDICAL ASSOCIATION, also by the Public Health Association; and

WHEREAS, At the last meeting of the AMERICAN MEDICAL ASSOCIATION a report presenting a bill was adopted, and at a meeting of the Public Health Association held in Philadelphia, Oct. 29, 1897, said bill to establish a department was also adopted; therefore be it

Resolved, by the State Board of Health of Indiana, that we heartily concur in the action of the Associations herein named and earnestly request the co-operation of all who favor sanitary reform to urge upon Congress the necessity of passing the measure, thus insuring a more efficient and uniform control of infectious diseases.

Ordered: That the Secretary shall have this resolution referring to a bill to establish a National Department of Public Health and to define its duties, printed. And that he shall send the same to every State Health Officer in Indiana, requesting said officer to use his influence to promote the bill, and he shall further send a copy of the resolution to each member of all State Boards of Health.

J. N. HURTY, Secretary.

The Vaccine Laboratories of Germany; A "Germ free" Lymph not yet Attained.—Dr. Huddleston of the New York City Department of Health, states that the best European laboratories of this kind are to be found in Germany. While calf lymph is almost universally used upon the Continent, in England very little progress has been made; the latter country has not as yet outgrown the experimental state. The laboratories of Germany are under government control. The percentage of successful vaccination in Berlin is 96.84; in Hamburg 94.85. The best laboratory in buildings and equipments is that of Cologne, which the author described at length. At Hamburg vaccination of 1700 primaries with "germ-free" lymph gave eight cases of skin eruptions. The Imperial Berlin Commission recently reported, that in its judgment, inflammatory appearances are due: 1, to the condition of the person vaccinated; 2, to the greater or less amount of effective lymph in the material applied, and 3, to the technic employed in the inoculation. The commission stated that inflammatory complications are especially frequent if the incisions made in the inoculations are numerous, long, deep and close together. It is a familiar fact that inflammation is more frequent in secondary than in primary vaccination. It is also unfortunately the case that a number of German reports state that quite enough disinfection of the arm by means of sublimate solution and ether before vaccination does not prevent all inflammatory complications, but in some cases has actually seemed to increase them. Nevertheless it has been a great advantage to vaccine production that practically "germ-free" lymph may be obtained; because the germs present, while as a rule non-poisonous, are it is thought injurious to the vaccine organism, and it is a fact that by employing "germ-free" lymph the so-called "purulence" in the producing animals, one of the former bugbears of the vaccine laboratory, has practically disappeared. Laboratory workers have about come to the conclusion that it is at present impracticable to produce a sterile vaccine, but two different and partially effective methods of bringing down the number of germs have been discovered. One method consists of centrifugalization of virus which has been diluted with water, and the second, of mixing the virus with varying proportions of glycerin. The former method reduces the number of bacteria present but does not entirely remove them; the latter is much more effective, and by means of it the number of germs in lymph as tested by making cultures on agar, can always be materially reduced within

a period which varies from a few days to a few weeks. Sometimes this does not secure sterility, but when old glycerinated virus is not sterile the inference simply is that the germs present are such as resist the action of glycerin; the bacillus subtilis, for instance, which is non-pathogenic is unaffected by glycerin. It may then be fairly stated that lymph practically, although not absolutely "germ-free," can be secured with considerable certainty. The results from the use of this so-called "germ-free" lymph, whether absolutely sterile, have not, however, secured freedom from the inflammatory complications of vaccine. On the contrary it is the general testimony given by those who have experimented at length with such lymph that inflammatory reactions occur in about the same proportion of cases as before this lymph was introduced, and also that not merely inflammatory complications are present, but occasionally vaccinal eruptions as well, as has already been stated above regarding the Hamburg experiments. Finally, it should be added that while every brand of vaccine has its own bacterial flora, the few germs which are common to almost all are very clearly non-pathogenic to men or animals. Repeated inoculations of germ-bearing lymph have been made in guinea-pigs, rabbits and other test-animals, and almost invariably without any pathogenic results.—*Medical News*, January 1.

ASSOCIATION NEWS.

Denver Accommodations.—The following is a partial list of hotels and rooming houses with rates agreed to for the Denver meeting of the AMERICAN MEDICAL ASSOCIATION, June 7 to 10, 1898.

Brown Palace Hotel, 17th Street and Broadway. Take 17th Street car, to Hotel. European plan, \$1.50 per day; American plan, \$3.50 to \$5 per day.

The Albany, 17th and Stout Streets. Take 17th Street car to Stout Street. American plan, \$2 to \$3.50 per day.

L'Imperial Hotel, 14th Street and Court Place. Take Colfax Avenue car to Court Place, American plan \$2 to \$3 per day.

Windsor Hotel, 18th and Larimer Streets. Take 17th Street car to Larimer. American plan, \$2 to \$3.50 per day.

The New St. James Hotel, Curtis Street, near 16th Street. Take 16th Street car to Curtis Street. American plan, \$2 to \$3 per day.

The Oxford Hotel, 17th and Wazee Streets. Two blocks above depot. European plan, \$1 to \$3 per day.

American Hotel, 16th and Blake Streets. Take 16th Street car to Blake Street. American plan, \$2 per day.

New Markham Hotel, 17th and Lawrence Streets. Take 17th Street car to Lawrence Street. European plan, \$1 per day and upward.

Metropole Hotel, Broadway near 17th Street. Take 17th Street car to Broadway. European plan \$1 to \$2, single room, per day.

Hotel Broadway, Cheyenne Street and Broadway. Take Colfax Avenue car to Cheyenne Street. American plan \$1.25 to \$1.50 per day.

The Vallejo, 1420 Logan Avenue. Take Colfax Avenue car to Logan Avenue. American plan, \$2 per day and upward.

The Devonshire, 14th and Logan Avenues. Take Colfax Avenue car, to Logan Avenue. American plan, \$1.50 per day and upward.

The Albert, 17th and Welton Streets. Take 17th Street car to Welton Street. European plan \$1 to \$1.50 per day.

The Aldine, 1013 17th Avenue. Take 17th Street car to Ogden Street. American plan \$1.25 per day.

The Richelieu, 1727 Tremont Street. Take 17th Street car to Tremont Street. European plan, \$0.50 to \$1.00 per day.

The Earl, 1430 Tremont Street. Take Colfax Avenue car to Tremont Street. American plan, \$1.50 to \$2 per day.

Glenarm Hotel, Glenarm and 15th Streets. Take Colfax Avenue car to Glenarm Street. European plan, \$1 per day and up.

The Bonaventure, 18th and Glenarm Streets. Take 17th

Street car to Glenarm Street. European plan, \$0.50 to \$1.50 per day.

The Drexel, 17th and Glenarm Streets. Take 17th Street car to Glenarm Street. European plan, \$0.75 to \$1.50 per day.

For reservation of rooms please apply to hotel direct. For especial information address, ROBERT LEVY, M.D., California Building, Chairman Committee on Hotels.

SOCIETY NEWS.

The American Medico-Psychological Association. The fifty-fourth annual meeting of the American Medico-Psychological Association will be held in St. Louis, Mo., May 10-13, inclusive. C. B. Burr, secretary.

The Fifth District Branch of the New York State Medical Association will hold its fourteenth annual meeting at 315 Washington Street, Brooklyn, on Tuesday, May 24, 1898. Gonorrhea will be the subject for papers, discussions, and reports of cases. Robert W. Taylor will open the subject by giving the pathology and treatment in males. J. W. S. Gouley will treat of urethral strictures, William E. Beardsley of gonorrheal rheumatism and Lawrence Coffin of gonorrheal ophthalmia in adults. William McCollom will discuss the "Moral Prophylaxis and the Ethical Duty of Physicians to the Public;" J. C. Bierwirth the "Medico-legal Responsibility of Physicians to Their Patients and Patients' Friends." L. Grant Baldwin will give the symptoms and diagnosis of gonorrhea in females and will be followed by Walter B. Chase and Frederick H. Wiggin on the palliative and operative treatment. N. L. North, Jr., will present the subject of "Gonorrheal Ophthalmia of Infants" and will be followed by R. Mathewson and L. A. W. Alleman on the same subject. N. W. Leighton, president; E. H. Squibb, secretary.

BOOK NOTICES.

An Epitome of the History of Medicine. By ROSWELL PARK, A.M., M.D., Professor of Surgery in the Medical Department of the University of Buffalo, etc. Illustrated with Portraits and other Engravings. One Volume, Royal Octavo, pages xiv, 348. Extra Cloth, Beveled Edges, \$2.00 net. The F. A. Davis Co., Publishers, 1914 and 1916 Cherry Street, Philadelphia; 117 W. Forty-second Street, New York; 9 Lakeside Building, Chicago.

This is an excellent work and should be in every physician's library, as up to a recent time the history of medicine has been greatly neglected, but within a few years numerous works have appeared on the subject.

The work is well illustrated, portraits being given of many of the noted medical men. It is not only of interest to physicians and medical students, but to laymen as well. And this brief work, while it does not aim to be anything but an epitome, gives a fair understanding of the subject.

It is open to criticism in some respects. Hardly enough credit has been given to surgeons of the Arabic period, but in the main there is little from which to dissent and as a whole we have nothing but commendation.

A System of Practical Medicine. By American Authors. Edited by ALFRED LEE LOOMIS, M.D., late Professor of Pathology and Practical Medicine in the New York University, and WILLIAM GILMAN THOMPSON, M.D., Professor of Medicine in the New York University. To be completed in four imperial octavo volumes, containing from 900 to 1000 pages each, fully illustrated in colors and in black. Volume III.—Diseases of the Alimentary Canal, Peritoneum, Liver and Gall Bladder, Spleen, Pancreas and Thyroid Gland, Chronic Metal Poisoning, Alcoholism, Morphinism, Infectious Diseases Common to Man and Animals, Miscellaneous Subjects. For sale by Subscription. Per volume, Cloth, \$5.00; Leather, \$6.00; Half Morocco, \$7.00. Lea Brothers & Co., Publishers, Philadelphia and New York, 1898.

The contributors to this third volume are: Richard Cabot, M.D.; Warren Coleman, M.D.; George Dock, M.D.; Fred-

erick Finley, M.D.; J. E. Graham, M.D.; H. A. Hare, M.D.; Walter James, M.D.; William W. Johnston, M.D.; Allen A. Jones, M.D.; Francis Kinnicutt, M.D.; Alexander Lambert, M.D.; J. Law, F.R.C.V.S.; George Roe Lockwood, M.D.; Henry Lyman, M.D.; W. T. McNutt, M.D., M.R.C.S. Edin., etc.; Allen M. Starr, M.D.; James Stewart, M.D.; Charles Stockton, M.D.; Victor C. Vaughan, Ph.D., M.D.

The topics include: Diseases of the alimentary canal; diseases of the peritoneum; diseases of the liver and gall bladder; diseases of the spleen; diseases of the pancreas; diseases of the thyroid glands; chronic metal poisoning; alcoholism; morphinism; infectious diseases and miscellaneous subjects. The high standard set by the predecessor of this volume has been maintained in the present and we have no hesitancy in recommending the book as conservative, judicious and instructive. There is a copious index at the conclusion of the volume which is well printed on excellent paper with clear type.

Outlines of Rural Hygiene. For physicians, students, and sanitarians. By HARVEY B. BASHORE, M.D., Inspector for the State Board of Health of Pennsylvania. With an Appendix on The Normal Distribution of Chlorine by Prof HERBERT E. SMITH, of Yale University. Illustrated with Twenty (20) Engravings. 5½ x 8 inches. Pages vi-84. Extra Cloth. 75 cents net. The F. A. Davis Co., Publishers, 1914-16 Cherry Street, Philadelphia; 117 W. Forty-second Street, New York City; 9 Lakeside Building, 218-220 S. Clark Street, Chicago.

This little work is intended to throw light in dark places and to call attention to the neglect of sanitary rules in districts outside of the great cities. The scope of the work is as follows: Water-supply, waste disposal, the soil, habitations, disposal of the dead and normal distribution of chlorine.

The work is well illustrated and is undoubtedly very useful for the classes for whom it is intended.

There is certainly room for missionary work in the direction indicated.

A Manual of Obstetrics. By A. F. A. KING, A.M., M.D. Seventh Edition, with 223 illustrations; pp. 574. Lea Bros. & Co.: Philadelphia and New York, 1898.

When a work has passed its seventh edition it requires but little additional notice except to say that it has been brought up to date and has in no wise degenerated; and the author says in his preface that in the present revision some errors and omissions have been rectified, and additions introduced; the chapter on "puerperal septicemia" has been rewritten, and throughout the work an effort has been made to accentuate the importance of antiseptic midwifery with more emphasis than formerly. This work, which has grown from the date of its first appearance, has now become a volume containing matter enough to make a book twice the size if printed in larger type, and indeed it may be said that the amount of material contained in this compacted form is more than equal to some more pretentious books.

The teachings of the writer are sound and judicious and that careful condensation which made the first volume a favorite with the profession is continued in this.

A Living Substance as Such, and as Organism. By GWENDOLEN FOULKE ANDREWS. Supplement to Journal of Morphology. pp. 176. Ginn & Co.: Boston. The Athenaeum Press, 1897.

This work is a philosophic study, from a biologic standpoint, of the living substance. The work was carried on partly at the Marine Laboratory at Wood's Holl, Mass., and partly at the University of Pennsylvania.

The rapidly changing protoplasm is an evanescent structure to fix and classify, and camera drawing of the finest structure-phenomena the author finds impossible. "Of the living substance-phenomena," says the author, "it is about as practicable to reproduce it as it would be to trace upon a wall reflections thrown from disturbed water. Some camera drawings of the tilose phenomena in starfish and echinus eggs were made, but such can show by direct tracing larger masses only of the sub-

stance and are in point of time and relation true but to a limited extent. It follows from the very nature of these phenomena, as will be seen, that they can not be traced; for while the hand follows the minutest portion the relations of the whole will have undergone a change with important transpositions and transmutations of both structure and substance. In point of minuteness also many of the facts which can be optically noted defy camera tracing since the finest steel point is still too coarse for the work."

Notwithstanding these defects, the existence of the visible protoplasm structure has given good definite results which the author sets forth at some length in the volume under consideration.

The Aphasias and their Medico-Legal Relations. By F. W. LANGDON, M.D., Cincinnati, pp. 42. Norwalk, Ohio, 1898.

This monograph is a paper read before the Ohio State Medical Society at its Fifty-second Annual Meeting at Cleveland, Ohio, May, 1897.

It is of great interest and well illustrated. The author concludes that in the case of aphasia, if the sanity of the individual is established any legal document should be recognized, when he can understand fully its nature by any receptive channel, viz., hearing, visionary or muscular senses, and can in addition express assent or dissent, whether this expression be by spoken speech or pantomime, or written speech: Opinions which must be regarded as sound.

Proceedings of the Kansas Medical Society. Paper. 104 pages. Topeka, 1897.

This volume contains the proceedings of the Thirtieth annual meeting held at Topeka, May 13, 14 and 15, 1896; also of the thirty-first annual meeting. The report, however, does not include the papers and discussions.

NECROLOGY.

CHARLES R. TABER, M.D., Fort Motte, S. C., January 27, aged 60 years. He was a delegate to Cuba, by the State, for the purpose of investigating yellow fever and its causes, and the best means of preventing its introduction into the State. In 1888 he was a delegate to the International Medical Congress in Berlin, and was for years president of the State Medical Association and at the time of his death president of the State Board of Health.

GERARD C. PAOLI, M.D., Chicago, January 29. He was born in Trondheim, Norway, June 23, 1815. In 1832 he went to Christiania and there pursued literary and scientific studies for two years, after having previously graduated from a university. In the middle of his post-graduate course he was appointed an assistant to the district physician. After six years' study in Christiania he went to Stockholm. One of the acquaintances he then made was Ole Bull, whom he afterward knew intimately in this country. Dr. Paoli resided in London for a while, making diligent observations in the hospitals, then came to this country. Twice he was president of the Chicago Medical Society, twice its vice-president, and he assisted materially in establishing the Woman's Medical College and the Scandinavian Medical Society.

ISAAC MASSEY, M.D., West Chester, Pa., January 31. He was born in 1838. His grandfather, Israel Massey, was a life-long resident of Valley Forge, where he owned the land upon which Washington's headquarters were situated. Dr. Massey was a member of the Board of Trustees of the House of Refuge at Glen Mills, one of the staff of physicians at the Chester County Hospital, a member of the College of Physicians and Surgeons of Philadelphia, and a member of the Pennsylvania State Medical Society and the Chester County Medical Society.

SAMUEL T. SPEES, M.D., Tuscola, Ill., January 29.—Edward W. Riley, M.D., Kansas City, Mo., January 27, aged 47

years. John Sarms, M.D., Gallipolis, Ohio, January 29, aged 73 years.—Louis Pagin, M.D., South Bend, Ind., January 20, aged 80 years.—Michael Talbot, M.D., Niagara Falls, N. Y., January 26, aged 52 years.—E. C. Johnson, M.D., Hammond, Ind., February 5.

MISCELLANY.

Antistreptococcus Serum.—Belfanti and Carbone have established that this serum protects only against infection by the same variety of streptococcus. The question of the variety of the streptococcus is therefore of supreme importance in treatment.—*Cbl. f. Chir.*, Dec. 31, 1897.

A Nurse Honored.—The decoration of the Legion of Honor has just been conferred upon Miss Bottard who for fifty-six years has served in the nervous disease service of the great Paris hospital of la Salpêtrière, under Charcot for many years, who ascribed much of his success to her unparalleled devotion. Several times, three years have passed without her leaving the premises.

A Double Current Urethral Sound.—A groove along one side of the canula, which is a glass tube about seven centimeters long and twelve millimeters in diameter, allows the fluid to flow back into the receptacle provided without soiling the clothing. A projecting rim on the outer end prevents the canula from entering farther than the anterior urethra.—*Bull de l'Acad. de Méd.*, December 21.

Change of Name and Location.—The British Institute of Public Health will be styled in future the Royal Institute of Public Health, and Her Majesty the Queen has been graciously pleased to accept the office of patron. The council of the Institute has conferred the Harben Gold Medal for 1898 upon Lord Playfair, and has appointed Dr. W. R. Smith the Harben Lecturer for 1899. The offices of the Institute have been removed to 197, High Holborn, London.

Improved Lodging Homes.—The new Mills House No. 1, in New York City, is a great success as a poor man's hotel, and is likely to pay a good dividend. In London the same field is being covered by the Rowton House, and another was opened three weeks ago which will provide good clean beds for 800 men, at sixpence a night, or for ten shillings a week, with board. They are always full, and they pay, for 800 sixpence a day means £7300 a year.

The Hoagland Laboratory, Brooklyn, N. Y.—Dr. C. N. Hoagland has again made a donation to the above named institution, by way of a New Year's gift, by the conveyance of a security valued at \$24,000. Dr. Hoagland's benefactions to the cause of scientific research are said to have reached a figure considerably in excess of a quarter of a million of dollars during the last ten years. Dr. Ezra H. Wilson, who has for four years been the bacteriologist in chief to the local department of health, has resigned from his sanitary position to devote his time fully to the conduct of this Laboratory.

Improved Appliances for the Sick.—A new lifting appliance fits directly on the four posts of the bed, which are extended upward for the purpose. The patient lies permanently on the broad linen support, parts of which can be unbuttoned as required to allow access to any part of the body. It adds very little to the weight of the bed. P. Jacobsohn has also devised a simple wheeled frame that can be applied to any bed to enable it to be wheeled lightly about. It consists of two light horizontal iron frames, forming two superposed hollow squares. The lower is fitted with rubber wheels. A stout jack-screw at each end turned by a single crank, pushes the two frames apart and raises the bed off the floor. Another appliance of his invention is a light iron frame with a jack-screw, which can be applied under the foot or head of the bed and raise

that end to any level desired without danger of jarring the patient. Iron hooks grasp the bed and the frame rests solidly on the floor.—*Deutsche Med. Woch.*, January 6.

Statistics of Anesthetics at the Italian Congress of Surgery.—Three deaths were reported, but two are dubious, and only one was a typical case of chloroform intoxication, out of 3760 cases of general anesthesia; chloroform was used in all but eight. Six hundred and thirty-seven operations without anesthesia were reported; 292 with local anesthesia. A case of icterus consecutive to chloroform was reported, with serious nervous phenomena, which grew worse with the administration of chloral, but gradually passed away (*Gaz. d. Osp. e d. Clin.*, November 14). Combining the Italian statistics for the last two years, there were thirteen deaths in 53,992 chloroform anesthesia, and one death in 2802 with cocain.

Coincidence of Epilepsy and Diabetes.—W. Ebstein reports several observations of epilepsy coinciding with diabetes mellitus decipiens, and urges investigation of the urine of epileptics, especially in the Jacksonian form, as the glycosuria frequently escapes notice.—*Deu. Med. Woch.*, January 6-13. We note also a communication by Orlandi in the *Gaz. de Osp. e d. Clin.* of December 26, reporting a case of Jacksonian epilepsy accompanied by an enormous amount of acetone in the urine and blood. He established experimentally that the intoxication could not be attributed to the acetone, but that the latter was simply a symptom of another intoxication.

Physicians in Public Life.—The present French Senate numbers thirty-nine physicians and three veterinarians among its 300 members, while in the Lower House there are fifty-eight physicians, two veterinarians and four druggists to the 581 deputies, a proportion of one to nine. In Germany the proportion is very much less—one to sixty-six (1893). In the last ten years France has had physicians in the cabinet; ministers of the navy, interior and of agriculture. Among the better known members of the legislature are Professors Cornil and Lannelongue, and the popular surgeon Labbé. Trelat, Trousseau and Malgaigne were also senators in their day. The French legislator is usually first the mayor of his town or occupies some other public office (in Paris, member of the city council), thus showing the remarkable interest taken by the medical men of France in public affairs and politics and the esteem in which they are held. (From Paris letter in the *Deu. Med. Woch.*, December 23.) Italy has twenty-three physicians in the legislature, including six professors.

The Passage of Solid Particles and Air from the Bladder into the Kidneys, etc.—Professor L. Lewin announces in the *Deutsche Med. Woch.* of December 23, that he has established by experimental tests that air and solid bodies (ultramarine blue or green rubbed into a gum arabic solution, etc.) introduced into the bladder, find their way by mechanical or peristaltic action, or both, through the ureters into the kidneys, and from there through the uriniferous tubules, the lymph spaces and the blood vessels into the circulation, the heart, pulmonary vessels and even the liver. If the renal vein is severed after being ligated toward the center, and ultramarine green is injected into the bladder under high pressure, it soon appears in the fluid issuing from the vein. He proves thus that there is natural communication between the bladder and the heart, which allows the passage of air and solid particles, much more of living micro-organisms, and explains many sudden deaths from embolism and certain general infections.

Spontaneous Sediment Formation in the Blood.—Biernacki adds to his previous communication in regard to this means of clinic investigation (*vide JOURNAL*, Dec. 25, 1897), that he has never known a case of functional neurosis to fail to present an abnormal sediment formation. In the neurosis in which neurasthenic symptoms predominate, with or without nervous dys-

pepsia, the sediment forms exceptionally slowly, and the assumption that this phenomenon depends upon abnormal processes of oxidation, is confirmed by the fact that the venous blood in these cases is much brighter colored than usual. On the other hand, functional neurosis in which the hysteric symptoms predominate, shows exactly the opposite; the sediment forms with extreme rapidity and the amount of sediment is small. These results have been constant in the thirty cases examined, and cast a new light upon functional neuroses, and possibly upon their etiology. They also furnish a new means to detect simulation. He asserts that abnormal sediment formation is the most delicate of all tests, as even one organ affected will disturb the sedimentation, although the individual is otherwise in normal conditions. In hyperglobular blood the sediment forms slower than in normal, while the process is abnormally rapid in blood poor in corpuscles and hydremic.—*Deutsche Med. Woch.*, December 30.

The Jewish Population of the United States.—The American Jewish Historical Society has published a note on the above subject, in which some interesting statistics are presented. Twenty years ago the first systematic attempt to obtain definite statistic information was made by the Board of Delegates of the American Israelites, with the assistance of the Union of American Hebrew congregations. Incomplete reports secured showed a Jewish population of 189,756. By 1880 these figures had increased to 230,257. The total population of the country in that year was 50,155,783. It is calculated that since 1880 something over 485,000 Jews have immigrated to the United States. This addition, together with the increase through births, gives at a conservative estimate a present Jewish population of 938,000. The total population of the country is now estimated to be 75,000,000. In other words, it is one-half larger than it was seventeen years ago, while the Jewish population is more than four times larger. The Jews are not numerous in agricultural States. Their greatest numbers are in States having large cities, as, for instance, New York, 350,000; Pennsylvania, 85,000; Illinois, 85,000; Ohio, 50,000; California, 85,000; Maryland, 35,000; Missouri, 25,000; New Jersey, 25,000; Louisiana, 20,000; Massachusetts, 20,000.

Importance of Chromatolysis. The complexity of the nerve-cell and the dissolution and disappearance of the chromatophilous elements, to which the term chromatolysis has been applied, were among the most interesting subjects treated at the last International Congress (*vide JOURNAL*, Vol. 29, pages 695 and 745). Recently, Van Gehuchten has demonstrated that this chromatolysis is observed whenever a sensory or motor fiber is severed, ligated or compressed. The motor fiber gradually returns to its normal condition, but the sensory fiber degenerates and disappears. He ascribes this difference to the fact that the lesion of the periphery prolongation of the sensory cell deprives the latter of all external excitation. External excitation is therefore evidently indispensable to the anatomic integrity of the cell, and it perishes without it. As excitation from the external world is thus indispensable to the preservation of the neuron, upon which all the tissues and organs depend, it follows therefore that the life of the nerve-cell, and hence the life of all the elements that constitute our organism, is impossible without excitation from without.—*Gaz. d. Osp. e d. Clin.*, January 11.

Condemnation of the Office of Coroner.—The following is a part of a recent presentment of grand jury of the County of Kings, New York: "We have also investigated the methods in vogue in the office of the coroners. It is proper, however, to say that we have not taken up the methods in vogue under the present coroners, but only for the time prior to their taking office. We recommend to the legislature of the State that the office of coroner be abolished. We believe, from our investigation, that the office is useless, that it has no practical

effect in the ferreting out of crime; that the methods in vogue in that office during the time of our investigation are open to the most severe censure; the manner of conducting the business was inefficient, and the powers of the coroners were delegated to subordinates whose chief functions seem to be to get rid of the business and collect the fees incident to the office, for their chiefs. We believe that the continuance of the coroner's office in its present shape, as the law now stands, will lead to further abuses; that the law governing the rights, duties and obligations of coroners is not clear nor specific; that the very fact that various interpretations as to the rights and duties of the coroners may be put upon the law by those who should be familiar with it, will lead to abuses which only the entire abolition of the office can wipe out."

Suture of the Tendons.—Delamare reports a case of secondary suture of the extensor tendons of the three last fingers to the extensor tendons of the index, it being impossible to find the central ends of the severed tendons. The functional result was excellent.—*Gaz. Méd. de Paris*, January 1.

"Virchow's Archiv" completed the fiftieth year of its existence December 29, with the one hundred and fiftieth volume. A banquet on this date in honor of Virchow and the jubilee of the *Archiv*, was arranged by a committee presided over by Professor v. Bergmann, to which the members of all the medical faculties and of all the medico-scientific societies in Germany were invited.

Unna's Prize.—There was no competition for this prize in 1897, consequently the amount offered, 300 marks, is doubled, and 600 marks are now to be awarded for the best contribution on the subject announced: "An investigation whether and to what extent all the stains considered specific for elastin will also stain elacin." Send communications to the care of Leopold Voss, Hohe Bleichen 34, Hamburg, before December, 1898.

Our Aryan Origin.—According to a recent communication to the Paris Société d'Anthropologie, based on the latest ethnic and philologic research, and archeologic data, including much personal work, Zaborowski locates the Aryan country in the plains of the north of Europe extending to the limits of Asia, and ascribes to the blonde Cymri the principal rôle in the founding of the Aryan race.—*Progrès Méd.*, December 25.

Potassium Permanganate and Argonin in Gonorrhea.—By combining these two remedies, Stark reports that a much more prompt and effective action is secured. The daily rinsing with the permanganate softens the tissues of the urethra and favors the penetration of the argonin, which is injected three times a day in a 2 per cent. solution.—*Semaine Méd.*, December 29.

Length of Life of Anthrax Spores.—It has been demonstrated at Professor Petrone's Institute of Path. Anat. at Catania, that anthrax spores retain their vitality twelve years, and not until after thirteen years were guinea pigs safe from infection by inoculation. But their virulence is not as great during the latter years, so that the larger animals and man could scarcely be infected by anthrax spores eight or ten years old.—*Gaz. d. Osp. e d. Clin.*, January 6.

Concentration of Therapeutic Sera by Freezing.—Dr. Buywid has been engaged in experiments with diphtheria and tetanus antitoxin preparations in order to obtain concentrated solutions. The dried preparations are, in the minds of many, unreliable and under certain circumstances may be dangerous. A partial evaporation of sera at a low temperature gives a cloudy product. A better method consists in freezing the remedy. The ice is clear and there remains only a small amount of a brownish fluid in the bottom of the glass. If the glass of serum is allowed to freeze slowly the upper layer is without color and contains little beside pure water. The lower layer is a clear, bright yellow and contains almost all of the antitoxin. The two are readily separable.—*Centralblatt für Bacteriologie*.

Birth in Coffin.—A woman was found drowned, six months pregnant. After burial a murder was suspected and the coffin reopened, when the inverted uterus was found between the thighs of the corpse with the body of a fetus 36 cm. in length. The two theories proposed: that the accumulation of gases in the abdomen forced out the contents of the uterus, or that this was accomplished by post-mortal contractions of the uterus, are both considered improbable by Bleich who reports the case.—*N. Y. Med. Woch.*, December 1, from *Vierteljahrsschrift f. Ger. Med.*

The Two-hundred Guinea Fee.—When railroads had become general throughout the country it was felt by some of the leading physician and surgeons of the metropolis that an easier, less tedious and less expensive mode of traveling ought in fairness to the public to be met by some reduction in the rate of remuneration, and after a full consideration of all the circumstances it was concluded in sequel to a conference between Dr. Paris and Sir Benjamin Brodie, on the part respectively of the College of Physicians and of the College of Surgeons, that a reduction of one-third would be fair to all parties and meet all the requirements of the case, and thus that a physician's journey of 300 miles would imply a fee of 200 guineas in the place of 300, as it had previously done.—The "Life of Sir Henry Hallford."

Riot over a Missionary Hospital.—At Jerusalem the Jews have been the causers of no little turmoil, and a missionary hospital of British extraction has been the storm center of trouble for this reason mainly, because the meat served to the patients was not known to be *kosher*. If the inferior rabbis could have induced or compelled the hospital authorities to employ Jewish slaughterers there would, it is stated, have been no riot, bloodshed nor arrests. A few pence difference one way or the other would have made the difference between peace or riot. The *kosher* argument, as it is called, is used as a convenient cloak for very trivial financial enterprises; a fraction of a cent per creature slain by the religious butcher, is sometimes all that comes into the coffers of the rabbi, and yet this picaresque profit may become the source of much contention, confusion and sometimes of crime from the Gentile standpoint of view.

The Diazo-Reaction in the Urine of Infants.—As the result of numerous and painstaking investigations, Unikow announces in *Wratsch* (Nos. 39 and 40), that the diazo-reaction never appears in the urine of healthy infants. Fever has no influence upon its appearance. It never appears in pneumonia, diphtheria, intestinal catarrh, chickenpox, otitis media, eczema of the face, inflammation of the lymphatics, congenital syphilis, bronchitis, laryngitis, pleuritis or rhinitis. On the other hand, it is invariably present in erysipelas and measles and the more pronounced as the disease is severe. As the disease subsides, the diazo-reaction diminishes. It was sometimes observed in the prodromal stage of measles, and it persists until the end in the fatal cases, having thus great prognostic value. *St. Petersb. Med. Woch.*, December 25.

Percussion of the Skull.—It was announced at the Italian Congress of Surgery, which concluded its sessions at Rome, October 30, that percussion of the skull is perfectly practicable and will be found a valuable aid in diagnosing. E. De Paoli and A. Mori have made an extensive study of the subject, and state that the sound obtained by percussion with the fingers is produced by the vibrations of the bone walls, the contents of the skull and the air in the buccal cavity. Any modification in the sonority indicates an intracranial lesion and also its exact location. The sound obtained by percussion of symmetric points is identical if both are normal. They introduced the yolk of an egg, blood and other substances, into the skulls of cadavers, and the variations in the percussion were instructive. Applying the results of these experiments to patients with circum-

scribed lesions, they diagnosed positively by percussion, the exact location of cerebral abscesses, hematoma under the dura mater, localized meningitis, etc., and the diagnosis was confirmed in every point by the operation or necropsy later. When percussion is painful they use the stethoscope placed on the bregma.

Memorial to Billroth.—The portrait memorial erected to Billroth under the arcades of the Vienna University was unveiled November 7, in the presence of a brilliant assemblage which included numbers of his former pupils who had traveled far to do honor to his memory. He is represented standing at the desk with the scalpel in his hand. We notice in the address of Professor Gussenbauer, his successor, the following tribute to an American: speaking of Billroth's famous motto, *Durch Klarheit zur Wahrheit*, which inspired all his scientific work, he added: "When the famous surgeon Samuel D. Gross of Philadelphia, was present at a lecture by Billroth, on 'Neoplasms,' he remarked to him, 'I congratulate myself on having heard your lecture; you talked to your students with such truth, such rare truth.' This testimony is sufficient, as it came from no less a one than Samuel Gross."

Can Order Surgical Examination in Divorce Case.—Judge Russell holds, at a special term of the supreme court, New York County, in the case of Cahn vs. Cahn, October, 1897, that, in an action for the annulment of marriage on the ground of physical disability of the defendant at the time of the marriage, and since continued, the court can direct a surgical examination of the person of the defendant, in aid of the charge which is the foundation of the action. The judge admits that the New York Civil Code does not provide for such an examination, Section 873 thereof referring only to examinations of the kind in cases of demands for personal injuries; nor does he find any decision of the courts of that State since the adoption of the Code of Procedure in 1848 which provides for such an emergency. On the other hand, the inherent power of the court has been held not to extend to an examination of the person by surgeons in an action for personal injuries. Nevertheless, he pronounces in favor of this extreme exercise of the directing power of the court, to be enforced, if necessary, by contempt proceedings. Without the exercise of such a power, he says, the court would be impotent to decree annulment of marriages obtained by fraud of this nature. The defendant could simply resist the sufficient proof, obtainable alone by an examination of his person, relying upon the well-known rule of the courts to refuse annulment of the sacred tie of marriage unless upon satisfactory proof, and thus hold the innocent consort to the perpetual burden of a marriage with a sexless husband.

Identifications of Organs for Analysis.—The evidence in a murder case fully identified and accounted for the whereabouts of certain organs from the time they were taken from the body of the deceased until they reached a Chicago toxicologist, except for the space of an hour or so when they were left sealed in the office of a physician, while he went to dinner, and while they were in transit, by the express company, to Chicago. If they were properly delivered to the express company for shipment to the toxicologist, in Chicago, as the evidence showed they were, this, the supreme court of Iowa holds, *State vs. Van Tassel*, October 1897, was sufficient to cover the period of time necessary to their shipment. When the physician referred to went to dinner, he left the jars, containing the organs he had removed from the body of the deceased, in his office, but he testified that they were locked up in a commode, and that he also locked the office door when he was away, and that no one was in the room while he was gone. The city marshal assisted the physician in packing the jars containing the organs taken from the body of the deceased, and, as soon as they were packed, the marshal took the box, and delivered it to the assistant

express agent, who held it in his possession and had it under his immediate supervision, until it was shipped to Chicago. The toxicologist received the box in the apparent condition in which it was when shipped, and analyzed the contents of the jars. Surely, holds the court, this was a sufficient identification to justify the admission of the toxicologist's evidence. That there was some little conflict as to the number of jars sent and received, the court does not consider of itself sufficient reason for rejecting the evidence.

The Antivivisection Bill.—The following has been mailed to each senator and congressman from Illinois:

JERSEYVILLE, ILL., Jan. 23, 1898.

To the Hon. ———. *Dear Sir:*—We, the physicians of Jerseyville, Ill., earnestly urge you to oppose the passage of Senate Bill 1063: Calendar 138; entitled, "A Bill for the Further Prevention of Cruelty to Animals, in the District of Columbia." Our reasons for opposition are these:

1. Its enactment would serve as a precedent for the passage of similar bills by the legislatures of the various States.
2. Such legislation would do irreparable harm to countless men, women and children.
3. The knowledge gained by experiment upon living animals enables us to save thousands of people that otherwise would have died.
4. The knowledge thus gained in regard to diphtheria alone, is enough to convince any one that the suffering inflicted upon the lower animals, to gain such a knowledge, has been amply repaid.
5. The aim of such experiments, is not to inflict suffering, but to ameliorate the suffering of mankind.
6. Legislation, such as Bill 1063, is directly opposed to the progress of science, the healing of wounds, and the saving of life. Therefore, we oppose it and sincerely hope that you will use your vote and influence toward its defeat.

Yours very truly,

Drs. C. DuHadway, J. S. Williams, Edward L. H. Barry, A. A. Shobe, Thomas A. Kingston, W. W. Estabrooke, C. R. Enos, A. K. VanHorne, A. A. Barnett, H. R. Gledhill, A. G. Porter, Albro B. Allen, J. W. Enos.

Doctors not the only Ones who Cannot Remove the Buried.—A North Carolina statute provides "That any person who shall without due process of law, or the consent of the surviving husband or wife, or the next of kin of the deceased, and of the person having the control of such grave, open any grave for the purpose of taking therefrom any such dead body, or any part thereof buried therein, or anything interred therewith, shall be deemed guilty of a felony." It was suggested by the defendants, in the case of *State vs. McLean*, they being the mayor and commissioners of the town of Burlington, with the keeper of the town cemetery, that the mischief intended to be suppressed by the statute was the desecration and robbery of the graves of the dead, and that the spirit of the statute did not, if its letter did, make it an offense for them to command, counsel, and procure the opening of a grave in an unpaid-for lot and the removal therefrom of the dead body to the free part of the cemetery. But the supreme court of the State declares, Nov. 9, 1897, that the statute is directed against all who disturb the last resting place of the dead, except those who act under the due process of law, or who procure the permission to open the graves and remove the body, from the surviving husband or wife, or the next of kin of the deceased, and of the person having control of such grave. Why, the court asks, should it be thought that the law should apply to those only who open a grave, or procure it to be done, and have removed dead bodies, for purposes of medical or surgical knowledge, or for purposes of larceny of anything buried with the body? If a surgeon can be convicted for employing a person to open a grave and remove therefrom a dead body, his purpose being to advance medical and surgical science, again it asks what reason can be urged

against the conviction of persons who command a grave to be opened and the body to be removed because the lot of land on which the deceased has been buried is not paid for by his next kin? It is hardly necessary to add, the court affirms a conviction of the defendants in this case.

New York as a Business Community and Dispenser of Charities.—

The Controller of the State of New York in a recent report points out that the per capita cost of government in New Jersey is \$1.60; in Pennsylvania \$2.42; in Massachusetts \$4.8; while in New York it is \$4.49. To this statement objections have been made regarding the basis of comparison and the unreliable factor in governmental figuring in general, but when the Controller indicates that in seventeen years the number of State commissions and departments has been increased thirty-six, and that the State expenditures, which in 1881 were \$9,378,214, amounted in 1897 to \$26,962,705, he inevitably poses the question whether there has been a corresponding return to the people in security and happiness. "The average citizen," says a secular contemporary, "is little, if any, better off, so far as the State government is concerned, than he was in 1881, and there has been no such increase in population as warrant a trebling of expenses." "So long as it is practical," continues this authority, "the people will not object to the cost. What they do object to is the building of palaces for public institutions. The governor himself has spoken of this as abuse, and spoken wisely. We want our dependents to have good care, and even some luxuries, but we do not want money wasted on great piles of architecture for the glory of the small town and to flatter the vanity of managers." Thus it appears that neither the public nor even its meek element, the medical community, are receiving the benefits to which they are entitled, while the objects of their care and indirect charities are not proportionately grateful.

Fruit as a Food for the Aged.—Sir Isaac Holden, who recently died in his ninety-first year, was neither a teetotaler nor a non-smoker. Sir Isaac was a man with theories. According to him the two great essentials for those who would live long and be healthy, are plenty of fresh air and plenty of fruit. His rule was never, if he could help it, to spend less than two hours a day in the open air. When he entered his first situation he said to his employer that he would be glad to have an hour daily in the afternoon for a walk. If granted he would ask for any holiday, or would make up otherwise for the time so spent. This was agreed to. Sir Isaac took his walks daily, and to this, he used to say, he owed both health and longevity. In addition to fresh air he believed in plenty of fruit. Sir Isaac was not a vegetarian. It was not meat but bread in which he abstained. Like Wesley, whose "Natural Philosophy" he studied when a boy, he saw in farinaceous food a thing to be avoided by the elderly. "I take for my breakfast," said a few years ago, "one baked apple, one orange, twenty grapes, and a biscuit made from bananas. My midday meal consists of about three ounces of beef or mutton, with now and then again a half-cupful of soup. If I take a little fish, I take much less meat. For supper I practically repeat my breakfast menu." The orange was his favorite fruit. Wine he eschewed; but on returning from the House of Commons to Queen Anne's mansions he had a tumbler of whisky and hot water before going to bed. He took no drink with his food, and this obliged him to masticate well. He smoked two or three cigars a day, from which he used to say that he derived much comfort and benefit.—*The Life Bulletin*.

The Ohio Colony for Epileptics.—The colony for epileptics at Gallopis, Ohio, was instituted in 1893, and Dr. H. C. Rutter, in a late number of the *Charities Review*, given an interesting account of the methods pursued there and the beneficent results achieved. He calls attention to the improvement in personal appearance and manners, produced by the mere fact

of association in which a patient who has been allowed in his isolated home to pay no attention to the desires or feelings of others finds that he must exercise self-restraint; "the social influences of the institutions are manifest even in the most degraded, and especially in the younger patients." Those who have had an epileptic in the family know what a burden of care is imposed by the constant necessity of watchfulness lest the patient fall in some spot where there are hidden dangers, or from high flights of stairs, etc. Dr. Rutter calls attention to the safety that comes from many of them being together. The onset of a paroxysm is marked by a peculiar cry, and in the colony the instant that cry is heard all else is dropped and the other patients rush to the aid of the one attacked and the result is that there is seldom a serious accident. In Gallopis no serious accident has occurred for more than two years among the more than eight hundred persons treated; and to show the value of this brotherly care, it is stated that among the 200 patients who have made temporary visits to their homes during that time no less than fourteen have met with fatal accidents and several others with serious ones. Taking all the patients in any one of these colonies together there is a great increase of happiness, and the weary unoccupied hours are lightened for them by employment, of which there are many kinds. The number of attacks have been reduced more than 300 per cent. among Dr. Rutter's patients, and at the close of the last fiscal year fifteen patients were discharged cured, *i. e.*, more than two years have passed since the last attack.

College of Physicians and Surgeons, New York.—The following changes in the faculty are noted in the *Columbia University Bulletin* for December: James Ewing, M.D., has been made instructor in clinical microscopy; Charles Norris, M.D., tutor in pathology; Frederick S. Ward, M.D., William R. Williams, M.D., and Frederick H. Floy, M.D., assistants in normal histology; William T. Neuman, M.D., assistant in bacteriology; Francis C. Wood, assistant in clinical microscopy; George P. Biggs, M.D., demonstrator of pathology. The new course in clinical microscopy, for fourth year students, has been inaugurated under the direction of Dr. Ewing. This is the first year in which hospital clinical instruction to small sections of students has been given, and the fourth year students express great satisfaction at the courses now under way. The chief feature of this instruction is the bedside study of disease, each student watching the progress of a number of patients in the hospital wards at Bellevue, getting full records of the cases from day to day, and having all the advantages of observation which are obtained by the resident staff in the hospitals. The increased facilities for instruction at the Sloane Maternity Hospital are also highly appreciated by the students. In the department of diseases of children, Professor Jacobi has added to his regular weekly clinic a new weekly hour, Fridays at 3 P. M., in the St. John's Guild Hospital, 155 West 61st street, to which he has been invited by the Board of Governors, to take classes of students for bedside instruction. The alumni and friends of the University are, however, well aware that systematic and thorough bedside instruction can not be attained before the college has its own hospital with daily attendance. The attention of alumni and friends is called to this fact in the same spirit in which the subject was emphasized by President Low in two of his annual reports. In addition to the regular clinic in orthopedic surgery, held by Professor Gibney, a special course to students, in sections of ten men each, is given by him this year for the practical demonstration of the fitting of surgical apparatus to deformities. Dr. Watson L. Savage was appointed advisor in physical training in June, 1897. During his college course at Amherst, Dr. Savage was very prominent in athletics. For several years he has been engaged in the work of physical training. Dr. Savage served three years on the Amherst Athletic Advisory Committee, and was medical director of the Columbia College

Crew for two years. The new director brings to Columbia the results of a long and varied experience in physical training. The medical school had 729 names upon its student's registry on Nov. 1, 1897.

A Missionary Hospital in the North.—The Dynevor Hospital has been established on the St. Peter's Indian Reservation in Winnipeg, chiefly for the benefit of a community of about 1200 families of red men. The sickness-rate having of late years been very heavy the missionaries of the Church of England opened a small hospital in March, 1896. This charity now consists in a dispensary, a surgery, two wards capable of holding a dozen patients, also a small emergency ward and several rooms that can be utilized for patients, when the other wards are overcrowded. The medical superintendent is Dr. Rolston, a retired fleet-surgeon, who served twenty years in the British Navy in the Baltic during the Russian war, on the North American, West Indian, Australian, and the New Zealand stations. In Canada, he volunteered as surgeon to Major Boulton's scouts, and at Fish Creek and Batoche, etc., he was conspicuous for his bravery on the field. During the first year of the hospital's existence over 1300 patients have been under treatment, thirty-two of these actually inside patients, although this latter gives a very imperfect idea, as many who ought really to be in the ward prefer to sleep away, and many during summer months come from long distances and camp (with their families) close to the hospital, all of whom require feeding, washing and nursing, more or less.

Camphor Intoxication.—The absolute fatal dose of camphor is said to be seven grams, states Barkholz in the *St. Petersburg Med. Woch.* of January 1, and then reports a case in which a young married woman took fifteen grams at once, in water, and experienced no ill effects for a couple of hours, when suddenly convulsions and acute mania developed. He was hastily summoned and applied the stomach-pump, giving later three grams of chloral and the same amount of potassium bromid. The patient rallied and recovered completely in two or three days. He explains the non-fatality of the dose by the probability that a large part of the camphor must have passed into the intestines during the two hours before its effects were felt. Here it was chemically changed into camphorol, and this was then oxidized into camphor-glycoron acid, which no longer possesses the intoxicating properties of camphor. Glycoron acid is a product of dextrin and other carbohydrates, and he mentions that in this case the patient had eaten a large amount of carbohydrates at supper, after taking the camphor. He therefore suggests that sugar administered in large quantities in camphor intoxication would be an efficient antidote. The symptoms of the present cases corresponded typically to the experimental tests with camphor described, only the convulsions were less prominent than the psychic disturbances.

Disturbed Innervation the Cause of Lack of Compensation in Valvular Insufficiency.—A series of experiments at Budapest, producing artificial valvular insufficiency and dividing the vagi, seem to demonstrate that alterations in the nervous system play an important part in preventing compensation in cases of valvular insufficiency. The vagus is the intermediary between the heart and the extracardiac nerve centers. After both vagi were severed in these experiments, the special nerve mechanism of the heart was sufficient to carry on the work of the organ unaided for a certain length of time, but this period was much shortened if, in addition to the severed vagi, there was also valvular insufficiency. Likewise, the heart carried on its work in spite of valvular insufficiency, when the innervation was undisturbed and even one vagus was left. The same results were obtained alike with cats, rabbits and dogs, leading to the inference that the cause of lack of compensation in a person with valvular insufficiency is some functional or anatomic disturbance in the cardiac innervation, rather than in the cardiac

musculature. Numerous clinic symptoms confirm this assumption: arrhythmia, etc., and Ott's statement that he found the nerve cells degenerated in cases of "incompensation."—*Deut. Med. Woch.*, January 6-13.

Tissue Changes Effected by Tuberculin.—Kasperek records the results of an important series of investigations into the action of tuberculin on healthy and tuberculous animals. His first object was to determine in some measure the relation between the reactions produced by different varieties of tuberculin. Preparations were made from human and avian tuberculosis by concentrating six to eight weeks' cultures to .125 or .1 per cent. of their bulk. It was found that eight times the quantity of bird tuberculin was required to produce the same effect in the experimental animals (guinea pigs) as a given dose of the human product; a good deal depended on the body-weight of the animal, and guinea pigs of as nearly as possible the same weight were selected in consequence. These precautions having been taken, the author was able to demonstrate that the tuberculin reaction was constant in diseased as distinguished from non-tuberculous animals. He next investigated the length of time which elapsed after infection with tubercle bacilli before the reaction was obtainable. When infection was accomplished by the injection of bacilli into the abdominal muscles the reaction appeared in thirty-six to forty-eight hours, at a time when no macroscopic lesion could be detected, though the bacilli were multiplying at the seat of injection. The fact that no reaction takes place at first shows that it is an actual tissue change in the animal and not the mere presence of bacilli which renders it so susceptible to the influence of tuberculin. This is confirmed by the fact that the substitution of an equal amount of living tubercle bacilli for the tuberculin gives no reaction whatsoever. When the tuberculous infection was effected by means of inhalation no reaction was obtained until after six daily exposures of an hour each; whenever it was obtained the animal eventually succumbed to tuberculosis. This shows the extraordinary diagnostic value of tuberculin. The last series of experiments consisted in the injection of tuberculin into the animals which had been weakened previously by diphtheria toxin. Fever resulted in these cases but was not of the same type as that constituting the tubercle reaction, than which it lasted at least five or six hours longer. Kasperek's conclusions are as follows: 1. The tuberculin reaction occurs very early (thirty-six to thirty-eight hours) in animals infected with tubercle, as soon, in fact, as the slightest amount of tissue change has taken place. 2. The activity of a tuberculin preparation varies with the source from which it is obtained. 3. The fever evoked by tuberculin in animals weakened, for example, by diphtheria toxin is distinguishable from the typical reaction by its greater duration.—*British Medical Journal*.

The Prospectus of the International Bibliographic Bureau has been received. Its aim is no less than to supply subscribers with a comprehensive card catalogue on the decimal system of all scientific publications, past, present and future on zoology, anatomy and physiology. It is not a commercial undertaking; the cost of subscription will merely cover the necessary expenses, never over two francs per hundred cards, and probably one franc or less, depending upon the number of subscribers. They will be supplied with the card catalogue on white cards. Brown duplicates are furnished on demand, which are substituted for the white cards as you acquire possession of the article or book designated on them. The white cards thus removed serve as a separate catalogue of your private collection. The bureau is associated with the "Bibliographia Anatomica" and the "Bibliographia Physiologica" edited by Prof. C. Richet of Paris. The price of the various parts of these are from six to ten francs each in book or card form. All anatomists, physiologists and zoologists are urgently requested to co-operate

with the bureau, and notify them of their publications as soon as they appear. This appeal is endorsed by many scientific investigators "especially Professor Bowditch." The decimal and catalogue system is too well known to describe, but we add an example to show its usefulness. If investigating various methods of counting the blood corpuscles we turn to *Physiologia* 612; under this we find *sanguis, circulatio* 612.1; *proprietates generales sanguinis* 612.11; *globuli* 612.111, and *numeratio lobulorum* 612.111.2, under which head we find the full titles of all the articles that have appeared on the subject, including those by Bleibtreu, Eykman, Marschner, Oliver and others with exact data where they are to be found, and mention of those among them which are replies to others.—*Concilium Bibliographum*, Zürich, Oberstrass.

The New Formalin Test for Bile Pigments.—Prof. A. Gluzinski writes to the *Wien. klin. Woch.*, December 30, that if a little formalin is added to human or animal bile it turns green in twenty-four hours, but if boiled for a few minutes, the emerald green appears at once. This can be changed into an amethyst violet by adding a few drops of any mineral acid, especially hydrochloric. Testing to see to which of the bile pigments this coloration could be ascribed, he found that if mixed with chloroform, the green changed to violet only when biliverdin was present. He also found that biliverdin, unlike the other bile pigments, showed two absorption bands in the spectrum after the addition of the formalin and hydrochloric acid. Alkaline solutions of bile pigments show a still more decided green on contact with formalin, changing to blue as the hydrochloric acid is added. To test urine for bile pigments, he has an equal quantity of urine in two test tubes, and boils one, after adding one-third formalin, when it turns green. Pouring this into a third test tube he adds a few drops of hydrochloric acid, when the color changes to violet. This test is extremely delicate, showing even in a 1 to 100-140 solution. This experience has convinced him that the bile pigment in icteric urine is almost exclusively biliverdin.

The Intracranial Circulation in some of its Aspects.—As the result of an experimental inquiry Elder (*British Medical Journal*, Nov. 13, 1897, p. 1414) has arrived at the following conclusions: 1. In the unenclosed skull there are two very evident forms of pulsation of the brain: *a*, the arterial; *b*, the respiratory; the former produced in the arteries, the latter in the veins. 2. In the closed skull the venous side of the circulation is of the greatest importance, and respiration acting through the veins takes an important role in the intracranial circulation. 3. During inspiration in the open skull the aspiration of blood from the cranial veins is accompanied by compression of the vessels and retraction of the brain. 4. In the closed skull a similar withdrawal of blood from the veins occurs, accompanied by decrease in the intracranial pressure. 5. There is no flow of cerebrospinal fluid from the spinal cavity to the intracranial cavity, either with respiratory movement or with arterial pulsation, as has usually been supposed. 6. In all probability, accompanying the emptying of the large veins during inspiration, there is dilatation of the arteries. (This may be accompanied by an increased rate of flow in the carotid artery as compared with the other arteries in the body above the level of the diaphragm, which are otherwise under somewhat similar conditions.) So during expiration the dilatation of the intracranial veins will be accompanied by narrowing of the arteries. The flow of blood through the capillaries will remain constant. 7. With arterial pulsation lateral pressure is exerted on the intracranial veins, leading to an increased flow of blood from the skull. 8. These movements of the veins, with respiratory movements and with arterial pulsation, will occur in the large veins leading into the intracranial venous sinuses, the walls of which are themselves incompressible. 9. Similar movements of alternating compression and dilatation of the arteries and

veins probably occur also in the spinal column, the cavity of which is to be looked on as being practically closed, just as the cranial cavity is. 10. In all cases of sudden increase of pressure affecting both cranial and spinal cavities there will practically be no variation in the quantity of blood present in the cavities. There will only be either: *a*, a variation in the amount of blood in one side of the circulation as compared with the other, arterial at the expense of the venous, or vice versa; or *b*, an alteration in the rate of flow through the capillaries. In rises of pressure lasting some time there may be alteration of the quantity of blood inside the cavities, resulting from alteration in the rate of secretion or of absorption of cerebrospinal fluid. 11. The point of importance in alterations of pressure inside the skull is the rate of flow through the capillaries. Steady flow through the capillaries, "adiamorphysis," as it has been called by Geigel, may go on under very low intracranial pressure or under comparatively high (Hill). 12. Increased intracranial pressure from an effusion into the cranium; *e. g.*, a hemorrhage, leads first of all to a flow of cerebrospinal fluid from the cranial to the spinal cavity, so giving a respite for a certain length of time to the intracranial circulation. If the effusion goes on, there is first, compression of the larger veins, which leads, after it has taken place to a certain extent, to interference with the flow of blood through the capillaries, and if the pressure continues to rise, to actual compression of the capillaries and true anemia of the brain. 13. When tracings are taken of the pulsations of the brain, with rise of pressure two forms of pulse wave may be seen, 1, when wave is less ample and still anacrotic, as it is under normal conditions; 2, where wave is higher and tends to become catacrotic. The former occurs much more frequently than the latter, and seems to be present in what may be termed "passive" increase of intracranial pressure, that is, when the intracranial pressure is increased from alteration in the circulation in the rest of the body. 14. In some conditions the intracranial circulation seems to vary independently of the circulation elsewhere. This would tend to show that although the blood vessels of the brain are not generally controlled from the general vasomotor center there must be some local mechanism for altering their caliber.

Strangulated Hernia in Infancy.—Strangulated hernia in infancy is of rather uncommon occurrence. Among 139,000 children treated in various hospitals, Stern (*Centralblatt für Chirurgie*, 1894) found no record of any case of herniotomy for strangulation: and of 1,900 cases operated upon for strangulated hernia in various hospitals, but thirteen occurred in children. Nussbaum operated upon two cases among a total number of 54,000 children under his care. A study of the statistics that have been collected shows that operations are more frequently called for during the earlier months of childhood than during the later, and that the symptom most commonly observed in children, or perhaps what should be called an associated condition rather than a symptom proper, is retention of urine. Reports of two cases of strangulated hernia in infants have recently appeared. The first is made by Moynihan (*Lancet*, Sept. 25, 1897, p. 788), who relates the history of a male child, twenty-two days old, in whom right-sided inguinal hernia had been noted from birth. Following an attack of crying the swelling increased in size, and attempts at reduction were unsuccessful. Within an hour the child had begun to vomit and had continued to do so at intervals that were growing gradually shorter. For about twelve hours no urine had been passed. Examination disclosed the presence of a tense inguinal hernia on the right side of approximately the size of a billiard ball. Attempts at reduction with and without chloroform anesthesia were unsuccessful, and operation was at once undertaken. The sac of what proved to be a congenital hernia, contained a little fluid and about ten or twelve inches of distended and discolored small intestine, with a point of strangulation at the neck of the sac. The inguinal rings were stretched with the finger and the gut returned, the operation being complete by performing a radical cure by Ball's method and by fashioning a tunica vaginalis from the lower part of the sac. A dressing of collodion and gauze was applied. The child passed urine during the operation. The after-history was uneventful and

recovery was speedy. The second case is reported by Cuff (*British Medical Journal*, Sept. 25, 1897, p. 811). The patient was a badly nourished and weakly child, 5 months old, that had been vomiting continually for thirty-six hours. There was complete constipation and a large hernia was present on the left side. The latter had been present from birth and was gradually increasing in size. The more recent enlargement was attributed to cough from which the little patient suffered. Examination disclosed the presence of a large, tense mass, which filled the left side of the scrotum and could not be reduced. The child looked extremely ill, kept up a continual cry, had a small, rapid pulse and vomited intermittently. The legs were kept drawn up on the abdomen. The vomit was a thin, yellowish fluid, free from fecal odor. The temperature was subnormal. Taxis failing, herniotomy was resorted to. An incision was made above and parallel to Poupart's ligament, the sac being opened and found to contain clear fluid and seven or eight inches of congested gut, which was tightly held at the neck of the sac at the internal ring. After incision of the ring and inspection of the gut, the latter was returned, with some difficulty, to the abdomen. The upper part of the sac was then dissected off the elements of the cord, a small portion left attached to the testicle and the upper part twisted up to the internal ring, its end being then brought through the internal pillar and attached there with a catgut suture. The wound was closed with a continuous silk suture and sealed with collodion and powdered iodoform. Small quantities of warm diluted milk were given at short intervals, and the child was dismissed on the twenty-second day.

The "Baldeo" Treatment of Yellow Fever.—Pena y Buelta of Trinidad, Cuba, announces that he has cured thirty-three in thirty-four severe cases by the following method: A pail (balde) of tepid water is placed at the bedside, with a kilogram of sodium sulphate, a tablespoon and a tumbler. Three tablespoonfuls of the sulphate dissolved in a tumblerful of the tepid water are administered to the patient; then, at an interval of one or two minutes he drinks other tumblerfuls, each alternate one containing a tablespoonful of the sulphate, until he has taken ten tumblerfuls and copious vomiting has been produced, with mechanical compression of the liver and gall bladder by the efforts at retching. A quarter of an hour after the vomiting has ceased repeat the process again; then half an hour after the last vomiting give the patient half a glass of water, not tepid, containing a spoonful of the sulphate; and fifteen minutes afterward another similar glass. If vomiting is produced, repeat at the same intervals until vomiting has ceased. This causes purging which cleanses the intestines. Six hours after the first attempt repeat from the beginning. Continue in this manner until the fever has vanished, using no other medication and allowing no food nor drink except water. "It will cure if commenced in the first four days of the disease, and it will cure many even at a later period. Three or four repetitions are sufficient; the eyes lose their excessive brilliancy and the skin feels cool to the hand; the patient is cured."—*El Monitor Médico*, No. 245.

Infant-Feeding.—From a survey of the attitude of the medical profession upon the question of infant-feeding, Holt (*Archives of Pediatrics*, Vol. XIV, No. 11, p. 816) summarizes as follows the points that may be considered as well established: 1. Good breast milk is the best infant food. 2. No substitute for breast milk can be trusted that does not furnish essentially the same elements, fats, sugar, proteids, etc., as breast milk. 3. These elements are found only in the milk of other animals, cow's milk being the only one that is available for general use. 4. Cow's milk requires some modification before it is fed to infants, because the proportions of the different elements, fat, sugar, etc., are not the same as in breast milk; and because some of these elements, notably the proteids, are not identical with those of breast milk. Among the important questions in infant-feeding that are still under discussion are: 1. Whether all milk should be heated and, if so, to what temperature and for what time; whether the purpose shall be mainly to destroy pathogenic germs, or to improve the keeping properties of the milk; also whether heating improves its digestibility or the

contrary. 2. What the standard of a "clean milk," bacteriologically speaking, shall be; also whether the exclusion of pathogenic germs by care and intelligence and a reduction in the number of saprophytic forms by scrupulous cleanliness in milk-production may not furnish what is needed; clean milk a few hours old, which will have all the advantages of Pasteurized milk without any of its possible disadvantages. 3. Whether such accurate modification as is measured by variations of small fraction per cent. is really essential or whether less accurate modifications may not give equally good results, provided the original milk is the best possible. Much is still to be learned regarding precise indications for varying the proportions of the different elements in milk-modification.

Louisville.

WATER.—Louisville is in a fair way to soon enjoy the luxury of a filtered city water supply. The water during the recent high stage of the river has been of a chocolate color, and was about the consistency of thin molasses, so heavily loaded with mud. This is the city's experience with every high water and the assurance that we will have filtered water before many months is most welcome news. The investigations which the water company have been conducting at the pumping station have proven the sand filter to be the most efficacious, taking into consideration the rapidity of work, and the state of the water at such seasons as this. The plan is to utilize the two big basins now used as reservoirs, as subsiding basins, where the water will be allowed to settle sufficiently to relieve it of much mud and other impurities. These basins are high enough to allow the water to pass mechanically into the sand filters which will be above the clear water basins. From the clear water basins, into which the water runs from the sand filters, the water will be pumped into an immense stand-pipe, of sufficient height to throw the water over the highest buildings in the city. There will be from eighty to one hundred sand filters, each from eighteen to twenty feet in diameter, and with three feet of sand in the bottom of each to catch the impurities before the water reaches the clear water reservoir, which will have a capacity of 25,000,000 gallons. The water will be treated chemically as it passes to the subsiding basins, this coagulation causing the mud to sink to the bottom and assist the filters in relieving the water of both impurities and bacteria, it being estimated that less than 50 per cent of bacteria will remain after the water reaches the mains. The entire cost of the improvements will be in the neighborhood of \$300,000.

Philadelphia.

THE COLLEGE OF PHYSICIANS.—The subject of the utility of placarding houses in which cases of scarlet fever and other infectious diseases occur has recently attracted considerable attention, and it was brought up on the second instant before the college by a resolution which had been referred from the December meeting, viz., "That a committee of three be appointed by the president of the college to wait upon the board of health and represent to it the sense of this college upon the subject, and to ask that the board cease its present practice of placarding all houses in which there occur such cases of contagious disease." The question was fully discussed, the subject being opened by a paper by Dr. Arthur V. Meigs entitled "Reasons why the Placarding of Houses in which are Persons Suffering with Scarlet Fever and some other Contagious Diseases should not be continued." The discussion was opened by Dr. James Tyson. At the same meeting Dr. George Enly Shoemaker read a paper entitled "Some Results of a Series of One Hundred Abdominal Operations;" and Dr. James Hendrie Lloyd reported a "Case of Cysticercus Cellulose of the Brain." Dr. Henry W. Stelwagon exhibited two cases of alopecia areata.

YELLOW FEVER IN THE DELAWARE.—A slight clashing of the national and local health authorities has arisen from the fact that the U. S. Quarantine Station at Reedy Island being tem-

porarily out of service, an infected vessel proceeded up the river until boarded by the State quarantine officials at Marcus Hook, and the latter immediately took charge and proceeded to enforce the full regulations. The schooner *John H. Tingle*, after unloading a cargo of coal at Kingston, Jamaica, had gone to Black River and taken on a load of logwood for Chester. Three of the crew were found to be ill with symptoms of mild yellow fever and they were removed to the hospital. The rest of the crew and ship were cleansed and disinfected, small fumigators generating formaldehyde being used. The government quarantine station at Reedy Island was at once reopened, January 21, and the officials sent a formal request that the ship be sent down the river and placed in their charge, which the State authorities politely declined to do. It was explained that the ship had passed the Marcus Hook government station during very stormy weather and had passed the Reedy Island quarantine because it was out of service.

DIPHTHERIA.—The yellow placard indicating the gruesome fact that "Diphtheria" is the unwelcome guest in the household, seems conspicuously out of place upon a physician's door post, and yet during the past week the friends of Dr. S. Weir Mitchell have been pained by seeing the formal notice of the Board of Health standing guard at his front door, unfortunately soon to be attended by the black flag which announced the death of his only daughter, a young lady just entering society. It is reported that Mrs. Mitchell has also been suffering with a mild attack of diphtheria. The sympathies of the entire profession and community are with the distinguished author and teacher in his great affliction.

Detroit.

AT THE REGULAR MEETING of the Detroit Medical and Library Association January 31, Dr. H. O. Walker read a paper on "Gastrectomy." After referring to Schlatter's unique case, which the Doctor denominated a "surgical freak," and reviewing the meager literature on this subject and commenting upon the use of the term gastrectomy as a misnomer for pylorotomy, the essential points in the surgical anatomy were set forth. Stress was laid upon the abundant arterial and venous supply, the numerous anastomoses of these vessels, the omental attachments on every side and the difficulty to be experienced in manipulating the duodenum or pulling down the esophagus without injuring adjacent organs. A series of twelve experiments upon dogs was reported in detail with results thereof. In two cases the Murphy button was used in joining the esophagus and the duodenum. In another case it was tried, but experiencing difficulty in this and the remaining cases the duodenum was closed either by a purse-string suture or by two rows of continuous sutures and an anastomosis with catgut sutures, made of the lower end of the esophagus at right angles with the lower end surface of the duodenum or upper end of the jejunum. The operations were performed under ether anesthesia. Strict asepsis was insisted upon, extreme care used in preventing and checking hemorrhage, but the wounds all closed without drainage. The subjects all died at intervals of from three to forty-eight hours after the operations. Fluid from two to thirty ounces was found in the cavity postmortem. In two cases the wounds were observably septic. In all the others that lived a sufficient length of time the rectal temperature and pulse were found to increase above the normal, indicating sepsis. After describing in detail the technique used, the Doctor concluded that in his experience hemorrhage was more easily controlled in the human subject than in dogs; that the operation is too dangerous for general application; that cases are rare in which it will be adopted, and that, judging from the history given, Schlatter's case was peculiarly adaptable. Success in the removal of cancerous growths of the stomach will depend upon early diagnosis. Dr. Walker presented a specimen of malignant growth of the cecum which he had that day removed from a man aged 38

years, with the following history: Patient observed in January, 1897, that his health was impaired from some cause unknown to himself or attending physician. In February a diarrhea set in and continued more or less until operated upon. In May a small tumor was felt through the abdominal wall above McBurney's point, when his physician diagnosed appendicitis. Jan. 27, 1898, the date when the Doctor first saw him, he presented a suspicious malignant cachexia with emaciation and persistent diarrhea. Tumor could be felt beneath abdominal wall without difficulty. At no time was the tumor painful. The method of operation was as follows: Straight incision six inches in length made on right border of rectus muscle. Digital exploration revealed tumor involving posterior wall of colon, extending to within an inch of ileocecal valve and upward about seven inches. The adjacent mesentery was also involved. Enucleation was tedious though hemorrhage was slight. Fourteen inches of the colon was extirpated and about two and one-half inches of the ileum. The end of the colon was closed and a right-angled implantation of the ileum into the side of the colon was made with catgut sutures. The Doctor stated that the fatality in this operation was great, about 40 per cent., largely due to shock; in fact, in several instances collapse of patient during operation was so great that it became necessary to desist from further interference. The growth had not as yet been examined microscopically, but clinically there could be no question but that it was carcinomatous.

AT THE REGULAR MEETING of the Wayne County Medical Society February 3, Dr. R. Bishop read a paper on "Special Treatment of Rectal Diseases." The Doctor believes that diseases of the rectum are too much neglected by the medical profession and so errors in diagnosis are quite frequent. He would have more thorough examination of the rectum in all cases where symptoms point to disease of the lower bowel.

AT A RECENT MEETING of the Faculty of the Medical Department of the Michigan University the Board of Regents was asked to instruct the superintendent of the University hospital to exclude from free hospital treatment those who are abundantly able to pay for medical service. To get an expression from the physicians of the State on this subject the different medical societies were asked to bring the matter up in regular session. This question came up before the Detroit Medical and Library Association on January 31 and before the Wayne County Medical Society on February 3, each society being unanimous in its condemnation of the methods now in vogue in the University Hospital and passed resolutions asking the Board of Regents of the University to comply with the request made by the faculty.

Hospitals.

OPENING OF THE MAITLAND HOSPITAL AT NEW YORK CITY.—The opening of the New York Hospital for scarlet fever and diphtheria, at the foot of East Sixteenth Street, took place December 30. The hospital consists of two pavilions, forming the letter "U," each two stories in height, and built of pressed brick. The laundry and fumigating apparatus are in the center. A special feature is the solarium for the use of convalescent patients. It is situated on the south side of the building and has a wall of heavy plate glass. There is also a roof-garden. The beds are of iron, the chairs and table of agate, and the shelves of glass. The hospital was open for patients on the first of January. There are no free beds.

EVANSTON, ILL., has just completed her new hospital, a three-story structure, at a cost of \$35,000.—The Cambridge (Mass.) Hospital is the recipient of \$1,000 in memory of a former patient.—The clinic room of the Notre Dame Hospital, Montreal, Quebec, was destroyed by fire January 29. The loss, \$5,000, was covered by insurance.—The will of the late Mrs. Josephine Mellen Ayer, widow of the J. C. Ayer, of patent medicine fame, leaves \$50,000 to the Pennsylvania Hospital, Philadelphia.—According to the will of the late Judge

John M. Scott of Bloomington, Ill., his estate of \$250,000 is eventually to found and establish a hospital in that city.—Under the will of the late Charles H. Contoit, a wealthy New York bachelor, a large estate valued at more than \$1,000,000 will fall to the benefit of nineteen hospitals and other institutions of relief and religion. Among the hospitals are St. Luke's Hospital, Tremont Home for Consumptives and St. Mary's Hospital for Children. These various beneficiaries are to receive share and share alike of the large residuary estate.

Societies.

The following meetings are noted:

Illinois.—Chicago Medical Society, February 2; McLean County Medical Society, Bloomington, January 28.

Massachusetts.—Norfolk District Medical Society, Brookline, January 25.

Michigan.—Grand Rapids Medical and Surgical Society, January 31; Northeastern District Medical Society of Michigan, Flint, February 4; Washtenaw County Medical Society, Ann Arbor.

Missouri.—City Hospital Medical Society, St. Louis, February 3; Jackson County Medical Society, Kansas City, January 27; St. Louis Medical Society of Missouri, February 5.

New York.—American Laryngological Association, Eastern Section, Albany, January 24; Otsego County Medical Society, Oneonta, January 18.

Ohio.—Northern Tri-State Medical Association, Toledo, January 27.

Pennsylvania.—Clarion County Medical Society, East Brady, January 25; Lycoming County Medical Society, Williamsport, February 1; McKean County Medical Association, Kane, February 2; Philadelphia County Medical Society, Philadelphia, January 26; Susquehanna County Medical Society, Halstead, February 1.

Texas.—Corsicana Medical Association, January 25.

Virginia.—Richmond Academy of Medicine and Surgery, January 25; Seaboard Medical Association, Norfolk, January 18.

Wisconsin.—Rock County Medical Society, Janesville, February 4.

CHANGE OF ADDRESS.

Archer, J. A., from Freeport, Ill., to De Lamar, Nev.
Ade, S. G., from 577 Fulton to 612 W. Madison St., Chicago.
Converse, E. D., from 100 to 126 State St., Chicago.
Dubs, R. S., from 100 to 92 State St., Chicago.
Foskett, W. A., from 1556 Milwaukee Av. to 298 Maxwell St., Chicago.
Jones, L. J., from 100 to 82 State St., Chicago.
Krotoszyner, M., from 41 6th St. to 700 Sutter St., San Francisco, Cal.
Looze, from Lincoln to Seymour, Wis.
Le Fevre, E., from Sidney, Ohio, to 823 Washington St., Boston, Mass.
Miner, S. G., from Jefferson Av. to 58 Cadillac Sq., Detroit, Mich.
Reynolds, G. B., from 711 Calvert to 809 N. Charles St., Baltimore, Md.
Spaulding, H., from 3141 Rhodes to 3351 Indiana Av., Chicago.
Schaefer, C. R., from 430 to 1202 Madison Av., Indianapolis, Ind.
Toron, M., from 637 Larabee St. to Palace Hotel, Chicago.
West, M., from Atlantic City to 722 Market St., Camden, N. J.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from January 29 to February 4, 1898.

Major Charles K. Winne, Surgeon, leave of absence granted on surgeon's certificate of disability is extended two months on surgeon's certificate of disability.

First Lieut. John S. Kulp, Asst. Surgeon, will report in person on Feb. 22, 1898, to the president of the examining board appointed to meet at Vancouver Bks., Washington, for examination as to his fitness for promotion.

Major Egon A. Koerper, Surgeon, is relieved from duty at Ft. Crook, Neb., to take effect upon the expiration of his present leave of absence, and will then report in person to the commanding General, Dept. of the Platte, for duty as chief surgeon of that Department.

First Lieut. Benjamin Brooke, Asst. Surgeon, is relieved from temporary duty at the Army and Navy General Hospital, Hot Springs, Ark., to take effect April 6, 1898, and will then report to Washington, D. C., and report in person on April 12, 1898, to the president of the examining board, for examination as to his fitness for promotion, and upon the completion of his examination will report in person to the Adjutant General of the Army for orders.

A board of officers to consist of: Lieut.-Col. William D. Wolverton, Deputy Surgeon General; Major John Van R. Hoff, Surgeon; Capt. Frank K. Keefe, Asst. Surgeon, is appointed to meet at Vancouver Bks., Washington, on Tuesday, Feb. 22, 1898, at 10 o'clock A. M. or at such time thereafter as practicable, for the examination of such officers of the Medical Department as may be ordered before it, to determine their fitness for promotion.

A board of officers to consist of: Col. Charles H. Alden, Asst. Surgeon General; Major James C. Merrill, Surgeon; Capt. George D. DeShon, Asst. Surgeon, is appointed to meet at the Army Medical Museum Building in Washington, D. C., on Tuesday, April 12, 1898, at 10 o'clock A. M. or at such time thereafter as practicable, for the examination of such officers of the Medical Department as may be ordered before it, to determine their fitness for promotion.

The following named officers will report in person to the president of the examining board appointed to meet at the Army Medical Museum Building in Washington, D. C., for examination as to their fitness for promotion, and upon completion of their examinations will return to their proper stations: First Lieut. Alexander N. Stark, Asst. Surgeon; First Lieut. Charles Lynch, Asst. Surgeon; First Lieut. Edward L. Munson, Asst. Surgeon; First Lieut. Charles E. B. Flagg, Asst. Surgeon; First Lieut. James M. Kennedy, Asst. Surgeon; First Lieut. Guy C. M. Godfrey, Asst. Surgeon; First Lieut. William F. Lewis, Asst. Surgeon.

No. 8.

ADDRESS.

THE OBLIGATION OF SECTION MEMBERS TO THE AMERICAN MEDICAL ASSOCIATION.

TOGETHER WITH A HISTORY OF THE SECTION ON LARYN-
GOLOGY AND OTOTOLOGY.

Chairman's Address delivered in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY W. E. CASSELBERRY, M.D.

CHICAGO, ILL.

The honored custom of an address from the chair affords opportunities for suggestion looking to the welfare of our organization which would not find expression in any set paper or general discussion. I might with propriety and no little pride point to the expansion in recent years of the department of laryngology and otology and the influence wielded by this Section of the AMERICAN MEDICAL ASSOCIATION in the development of these sciences. I might dwell on the advantage of the fellowship and acquaintance which is engendered by our annual assemblies, the opportunities afforded to associate the personality of the author with the subject matter of his essay and to hear his defense if criticised in debate. But our present gathering is in the nature of a semi-centennial reunion and it is fitting, in fact it has been suggested by the Committee of Arrangements, that in each Section a brief historic sketch should be presented in recognition of the past and as a guide for the future. In the case of our own Section, one of the youngest, this history need not detain us long, and before proceeding therewith I would refer briefly to another topic: "The obligation of Section members to the ASSOCIATION as a whole," which seems equally appropriate at this fiftieth anniversary, as it particularly concerns the future welfare of the ASSOCIATION.

I have noticed on the part of Section members, a wide-spread disposition to refrain from participation in the proceedings of the general meetings. A few are overcome by modesty in the presence of men better versed in parliamentary tactics and perhaps, in years, their seniors: many are so engrossed in the strictly scientific aspects of medicine as to be more than willing to leave in other hands its material prosperity, while still others affect a disdain of what they are pleased to term "association politics." These sentiments are neither fair to the ASSOCIATION nor to yourselves, for as members of the general body you are not only responsible for, but bound by its action. The program reserves time for attendance and I would urge upon Section members the forethought to qualify in advance as voting delegates, to interest themselves in these meetings and to exercise the franchise. There, are discussed those larger and wider subjects relating to

general medicine, surgery and sanitation, continued familiarity with which serves to broaden the mental trend, and there also are enacted resolutions pertaining to professional policy and ethical principles.

Some have decried the necessity for any "Code of Ethics" such as is formulated by the AMERICAN MEDICAL ASSOCIATION, but its observance in the past has maintained individuals in closer touch with the great professional body and facilitated on the whole the affiliation of State and county societies. But its purpose is unification, not discord, and while exemplary, in every article save possibly one, the unhappy fact remains that this single clause has served to estrange the members and sympathizers of a prominent New York medical organization, who honestly differ in opinion. I am not presuming to pass upon the propriety or impropriety of this clause, the point I urge being that in order to secure adjudication of this and other important questions by an actual or representative majority of the ASSOCIATION, the Section members should participate to the fullest extent in the proceedings of the general meetings. The very men who find their highest interests in the Sections, those most potent in promoting the satisfactory numerical and scientific status, which on this occasion we celebrate, are best qualified to judge of modern professional needs. On all important questions let them express a majority verdict and then let every member loyally acquiesce.

Historical Sketch of the Section.—For several years prior to the formation of the present Section of Laryngology and Otology at Cincinnati in 1888, the upper respiratory tract had been represented in the Section of Ophthalmology, Otology and Laryngology, but under this composite arrangement the subject languished, for at the Chicago meeting in 1887, where your present chairman first acquired membership, only three papers pertaining to it were read. Meanwhile an agitation headed by Dr. W. H. Daly of Pittsburgh, was in progress for the separation, not only of laryngology, but also of otology, from ophthalmology, and the coupling of the former together in accordance with natural affinities. There would have been no objection to the independence of laryngology, but one is curious to discover by what *finesse* the ophthalmologists were finally induced to part with otology in their organization, for at that time every ophthalmologist was also an otologist. I am indebted to Dr. Daly for the explanation. He says: "For some years I had labored to this end finding it quite impossible of accomplishment, but at Cincinnati, with the efficient aid of Dr. X. C. Scott of Cleveland, an ophthalmologist, or rather from his personal friendship for me, I got him to withdraw his opposition. Dr. Seiler was there and helped us much. At the election of officers there were fifteen or sixteen present. They thought I (Dr. Daly) should be the first president and I being very desirous of giving the new child a

good start in the world, was anxious to have Dr. Ingals for secretary, and I made no mistake."

In the official record of the fourth day of the general meeting at Cincinnati in 1888, is found this entry: "Dr. Wm. Porter of Missouri and others called up the amendment to the constitution offered by Dr. Carl Seiler in 1884 and now asked for by the Section of Ophthalmology. The action was agreed to and a new Section of Laryngology and Otology was created."

The first meeting under the new organization was held at Newport in 1889, where the auspiciousness of the occasion was noted in an excellent address from the Chair entitled, "Marking an Era in Laryngology." At that meeting Dr. J. H. Bryan of Washington gave promise of the fame he has since acquired in the treatment of affections of the collateral sinuses of the nose in a paper on "Abscess of the Antrum." Dr. J. O. Roe of Rochester was one of the first to note the importance of the lingual tonsil under the title "Glandular Hypertrophy at the Base of the Tongue," while Dr. Jonathan Wright indicated the pathologic trend of thought, which has since distinguished him, in a study of "Nasal Bacteria in Health." Drs. Lawrence Turnbull, J. N. Mackenzie, C. W. Richardson, W. Freudenthal and others were represented, altogether ten excellent papers being contributed at the initial meeting eight years ago. A glance at our present program shows growth; this number of ten has been multiplied by eight, certainly a satisfactory development.

In the following year, 1890, at Nashville, Dr. J. O. Roe presided as chairman and the late Dr. F. H. Potter as secretary. The meeting is memorable chiefly by reason of "positively the last appearance of the ancient controversy over the identity or duality of croup and diphtheria. Fortunately Klebs and Löffler, by bacteriologic studies have made it unnecessary to longer discuss that point. In 1891, at Washington, Dr. Chas. H. Burnett made an early report on the progress of aural surgery in an important direction entitled, "Excision of the Membrana Tympani, the Malleus and Incus as a means of Treatment in Otitis Media Catarrhalis Chronica and in Otitis Media Purulenta Chronica." Dr. Carl Seiler served as chairman and Dr. A. B. Thrasher as secretary. In the following year, 1892, at Detroit, Dr. Burnett presided and terminated his address with this excellent injunction: "Let us assemble here, impart to one another what we know and aid one another in the search for more truth, for in the words of Lessing, 'Not by the possession of truth, but by the search after it are the faculties of man enlarged, and in this alone consists his ever growing perfection.'"

The meeting at Milwaukee, in the year of the Columbian Exposition, under the leadership of Dr. E. L. Shurly as chairman and Dr. J. E. Boylan as secretary, is memorable for a faithful adherence to a lengthy scientific program, notwithstanding the distractions of the World's Fair in a neighboring city. Dr. Herman Knapp's paper on "Cases of Empyema of the Ethmoid Cells and Sphenoid Sinuses" was one of the earliest and most convincing contributions to the study of ethmoiditis, a phase of rhinology since recognized as of transcendent importance.

The assemblies at San Francisco in 1894, Baltimore in 1895, and Atlanta in 1896, over which Drs. E. F. Ingals, J. F. Fulton and G. V. Woolen, respectively presided as chairman, and J. F. Fulton, T. J. Gallagher and M. R. Ward as secretary, are all of such

recent memory as to render special mention unnecessary, except to testify to the enthusiasm, earnestness and equally high standard of their contributions to the great fund of medical lore.

Gentlemen of the Section of Laryngology and Otology now assembled in ninth annual session, may I trust that this brief record of our past may serve as an inspiration for the future. I see before me many familiar faces, men to whom I extend sincere assurances of appreciation for the high honor which they have conferred upon me, but I see also others, men who are identifying themselves for the first time with our Section, and to them I extend the right hand of fellowship with our warmest welcome. In the search for more truth, let us profit liberally by each other's experience and endeavor to realize Emerson's conception of power: "A cultivated man, wise to know and bold to perform is the end to which nature works."

ORIGINAL ARTICLES.

THE SO-CALLED BLEEDING POLYP OF THE SEPTUM.

Presented in the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY NORVAL H. PIERCE, M.D.

CHICAGO, ILL.

I have been constrained to select this subject for my paper because in looking over the literature I have found but few instances of American writers having recorded cases of this pathologic condition. That the subject is important is proven by the circumstances surrounding my first case, the history of which is given below.

The patient was a male child, 6 years old, living in the southern part of Illinois. Six months before I saw him he had been operated on for a tumor of the septum, which had bled at frequent intervals for two months previously. The neoplasm was diagnosed sarcoma, was removed with a snare, and the toxins used. There had been the usual reactions and after two months the child was pronounced cured. But the bleeding having returned, the child was brought to me. On examination I found a tumor the size of a large pea projecting from the septum on the left side two mm. from the floor of the nose and about at the point where the triangular cartilage joins the vomer. The attachment was pedunculate. The color of the tumor was dark bluish, intermingled with red. It bled freely when touched with a probe. The tumor was removed with the cantery snare. The bleeding was unusually profuse, but was easily controlled by pressure. As I suspected the nature of the case I did not cauterize the base any further. The subsequent microscopic examination confirmed my diagnosis. It was what is known as a bleeding polyp of the septum or *fibroma polyposum fungoides teleangiectodes (septi narium)*.

The second patient was a maiden 15 years old, healthy and well nourished. She complained of discharge from the nose and recurrent hemorrhages which showed a tendency to correspond with her menstrual periods. On examination I found a tumor projecting into the left chamber from the septum a few millimeters above and a little anterior to the attachment of the former. It was the size of a French pea, markedly pedunculated and bled easily when touched with a probe. The tumor was removed, but not cauterized.

The patient disappeared from observation for a year. She then returned, with a history of frequent attacks of copious epistaxis. Indeed, in appearance she was quite anemic, and microscopic examination of the blood proved this to be a fact. Examination showed a recurrence of the tumor at the same place. It was again removed with a knife, and the base cauterized thoroughly with chromic acid. It did not recur, the epistaxis ceased and the patient immediately recovered from her anemia.

I present herewith microscopic slides from both of these cases. From the second I have a microphotograph.

We have then a subject that, viewed either from a theoretic or practical standpoint, is of especial rhinologic moment. We have not here a myxoma. This may be detected by its external appearance *in situ*. Again, we do not have the epistaxis from the myxoma. I believe Mackenzie's dictum to be right that "only in very rare cases is the septum the site of the affection." He evidently referred here to the myxomatous

twenty-one cases, among which I include my own, in fourteen the growth occurred on the left side, in seven on the right side.

As to sex, we see that Schadowaldt tends to ascribe great importance to the influence of sex. Out of fifteen cases in which the sex was ascertained eleven were females and four males. So that it would appear that the growth occurs with much greater frequency in females than in males. That it occurs more frequently about puberty there can be no doubt. The second decade of life seems to be especially prone to it, eight cases occurring between the ages of 20 and 25. One of my cases, the 6 year old boy, is the youngest patient reported that I am aware of; 51 is the oldest.

The shape, surface, color and mode of attachment of the tumor are constant within narrow limits. It is round, is finely or coarsely granular, according to the age of the tumor, a dark bluish, purplish or reddish color, and is attached by means of a very short and, in comparison to the bulk of the tumor, slender

or hyperplastic variety. In short, we have a pathologic manifestation. It always develops on the tissue covering the triangular cartilage, the same region which is the site of that strange process, the idiopathic perforating ulcer, the nature of which I believe to be still unrevealed.

Victor Lange in 1892 drew attention to the disease in a contribution to the *Wiener Med. Presse* (No. 52), and reported six cases.

In 1893, Otto Schadowaldt (Laryngologische gesellschaft zu Berlin) reported three cases.

In the same year Arthur Alexander reported three cases occurring in the practice of B. Fraenkel.

At the same meeting Max Scheier reported two cases and P. Heyman reported five cases.

With my two the total is twenty-one cases.

The great frequency with which these tumors were situated on the left side of the septum was remarked on by Lange; out of the six cases reported by him five were on the left side. And this peculiarity is still borne out by further experience. Out of the

pedicle. To the unaided eye the large tumors may appear to have a broad base of attachment, so short is the pedicle, but the probe gives more accurate information. In size it may vary from that of a small lentil to a hazel nut.

The most constant symptom is recurrent hemorrhage. Whatever the size or age of the tumor, this is always present. The epistaxis may be great or slight. When the tumor reaches dimensions sufficient to block up the nasal chambers, symptoms of nasal dyspnea may arise.

The microscopic pathology is emphasized by the accompanying cuts.

Dr. G. Fuetterer examined the specimens for me and gives the following description:

Specimen 1. The surface is covered with polymorphous epithelium arranged in a single layer for the most part; in places, however, the epithelium is increased to several layers. Beneath this the ground substance commences, which viewed with a low power appears to be homogeneous throughout the whole tumor. Under a higher power, however, the fibrillary character is discerned. Equally distributed through this ground substance are large spindle-shaped cells, having large deeply stained nuclei, which have been cut in all directions, showing their

interwoven arrangement. The tumor is highly vascularized, and in the center are numerous cavernous spaces, lined with flat endothelial cells. Specimen 2 shows nearly the same morphology, except that the blood in the cavernous spaces may be much more readily demonstrated.

Treatment: The tumor should always be removed. Victor Lange recommends the sharp spoon, but this method is liable to spoil your specimen. The snare, hot or cold, will serve very well; if the wire be thin and flexible hardly any difficulty may be experienced in extirpating it *in toto* with one attempt. Then too,

the hemorrhage is liable to be profuse, and before trying extirpation we should be prepared for this. A small quantity of ferripyryn in powder on a piece of cotton, held against the bleeding point, will cause the hemorrhage to cease instantly. The base should be well cauterized with chromic acid.

DISCUSSION.

DR. FREUDENTHAL—Dr. Pierce did not find any mention of similar cases in American literature. Dr. Roe and Dr. Cobb have published cases, and I also published two cases, two years ago. One of my cases was an angioma. Regarding treatment, I apply my nasal bag filled with ice, thus preventing severe hemorrhage. This I did with much success in one case, a few months ago.

DR. COBB—I think bleeding polyp of the septum is known under the head of angioma, and about eighteen cases are reported. At the Pan-American Congress I reported a case with the literature as far as I could learn it. In this case there was no recurrence, but I believe that angioma does sometimes degenerate into sarcoma.

DR. ROE—As a case of angioma of the nose which I reported three or four years ago has been mentioned in the discussion, I will simply say that the growth was exceedingly vascular and occupied the greater portion of the left nostril, extending about two-thirds toward the posterior portion. I first tried to remove the growth with a galvanic cautery snare, but the attempt was followed by such profuse hemorrhage as to necessitate the packing of the nose. I then tried the cold wire Jarvis snare and succeeded in removing the growth without hemorrhage. The patient was a man about 60 years old. After encircling the growth with the snare I instructed him how to turn the nut on the snare so as to cut through very slowly, and to stop the instant that any bleeding occurred, and when this ceased to turn the nut again. In this manner we consumed I think about two hours in the removal of the growth. After the removal I cauterized the base with chromic acid. After about six months there was a slight recurrence of the growth, which I removed in the same manner. I then lost sight of the patient, but about six months afterward learned that he died somewhat suddenly of anemia, characteristic of malignant growths. In this case the tumor started as a purely benign growth, as a microscopic examination of the portion first removed showed it to be a true angioma; while that which reappeared six months later showed sarcomatous elements, indicating that the growth had developed from a benign to a malignant one. We can not, however, positively say that the malignant elements may not have been in the deeper structures or in the base of the first growth, although at that time they were not apparent.

DR. PIERCE—My case was neither an angioma nor a sarcoma but a telangiectoma. I am opposed to the idea of a benign tumor degenerating into a malignant tumor.

SOME NOTES CONCERNING THE INFLUENCE OF SEXUAL EXCITEMENT UPON INTRA-NASAL DISEASE.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CHARLES PREVOST GRAYSON, M.D.

LECTURER UPON LARYNGOLOGY AND RHINOLOGY IN THE DEPARTMENT OF MEDICINE, UNIVERSITY OF PENNSYLVANIA.
PHILADELPHIA, PA.

When some certain offense against personal hygiene is generally recognized as one of several possible contributing causes of a disease, it would seem but reasonable that inquiry concerning it should become a matter of routine, and that in the event of its complicity, it should receive in the plan of treatment the degree of prominence it merits. It is a matter of common knowledge that sexual excitement, frequently repeated and prolonged, can occasion a great deal of vascular disturbance within the nose. With the production of such excitement through the olfactory sense, I am not now concerned. It is with the reverse of this phenomenon that this paper is to deal. A fugitive coryza quickly following upon the heels of a venereal debauch, is an instance of this, though it is a more than usually pronounced illustration of the effect of erotic excitement upon the nasal vasomotor mechanism. Lesser degrees of the same effect, however, are of much more frequent occurrence, I suspect, than many of us believe, and it is because of their frequency and the influence they exert in aggravating existing nasal disease and in hampering the action of local or general treatment directed to its cure, that they become worthy of some special study.

Among the whole of our patients, it is in but a comparatively small number that we find sexual excitement an active cause of trouble. For the sake of convenience, they may be grouped within two fairly well defined classes. First we have a number of young people whose exposure to it is largely innocent—one might almost say legitimate. I mean those who are on the brink of wedlock, those who are availing themselves of the privileges which custom accords to the preliminary betrothal. Thackeray, in his "Shabby Genteel" story, refers to them as "those who are legally engaged in sighing, gazing into one another's eyes, hand-squeezing, kissing, and so forth (for with such outward signs I believe the passion of love is expressed)." This transition stage between celibacy and marriage is one of acknowledged risk. Long engagements have, for many excellent reasons, been denounced time and again, and the intimacy, the excess of tenderness which too commonly accompany them, are accountable for much suffering both immediate and remote. As long as "the flesh and the Devil" are mixed up with human love affairs, so long as the average man's love is so strongly sensual and so feebly spiritual, so long will protracted engagements be baneful.

It will be my endeavor to show by a single example how the nose and its diseases may be affected by the emotional turbulence of this pre-nuptial period. It is that of a young woman whom I first saw in October, 1893. She had had attacks of hay fever in each of the three preceding years and following the one of 1893 she had developed symptoms of asthma. The nasal examinations disclosed a pair of turgescent inferior turbinates, while those immediately above them were found greatly hypertrophied and along the

lower margin of the left a fringe of budding polyps. These latter were thoroughly eradicated with the curette and the bodies themselves reduced by a few repetitions of chromic acid cauterization. The erectile tissue of the lower turbinates regained its full contractile power under simple astringent medication, the asthmatic paroxysms ceased, and the next two years passed with no recurrence of the hay fever. The early months of last year, 1896, were spent in Florida, and when my patient returned to Philadelphia she was wearing an engagement ring. The man in the case was barely twenty-five, a veritable Romeo in the ardor of his passion, and blessed with enough health and virility for two ordinary men. The engagement had been of but slightly more than two months duration when the young woman reappeared in my office with a complaint of renewed nasal discomfort. The middle turbinates were again markedly hyperemic and the lower greatly engorged and prominent. Two or three weeks of the local treatment that had previously been successful in reducing these latter, made very little impression upon them now, and a threatened return in the early summer of the hay fever symptoms induced me to send for the young man and persuade him to assist me in my effort to relieve the sufferer, by becoming considerably less demonstrative of his affection for her. Parenthetically, it may be hinted that sexual intercourse even though carried to considerable excess, is less provocative of damage to the nasal erectile structures, than frequent and prolonged sexual excitement which remains ungratified. For so young a man this one received my remonstrance very sensibly, exercised more self-restraint than I had expected, and with the result that within a couple of weeks the engorged turbinates had shrunk almost to normal, the hyperemia of the middle ones was scarcely noticeable, and there was an entire subsidence of nasal symptoms. The inference is unmistakable. Nothing would be gained by the addition of other examples more or less reiterative of this one, but I may be pardoned for alluding to the tact that is essential in securing the co-operation of one or both of the young people without hurting their feelings or giving any offense. A bachelor is by no means necessarily a misogynist, and I would not be suspected of wishing to dim the brightness of "love's young dream," but if one of the dreamers chances to have any catarrhal condition of the upper air tract, a few judicious words counseling patience before and moderation after marriage may, if heeded, be preventive of a decided aggravation of such condition. I pass to the consideration of a second, the members of which, however, are far from being as innocent as those of whom I have just spoken. It is composed of the man-about-town, single or married, youthful or mature, the sybarite, the voluptuary, the libertine. Whatever we may choose to call him, he is a very numerous personage and though he may escape those specific diseases which so frequently roughen the way of this variety of transgressor, yet, sooner or later, his nose may become the humble agent of retributive justice. The man who enters a physician's office with a venereal disease anticipates the kind of questions he will be asked and is generally willing to answer them unreservedly, but he who comes to the rhinologist with merely a complaint of nasal respiration, of more or less rhinorrhea, and of, perhaps, some dull frontal headache, is apt to be astonished and, not unlikely, resentful, if he be closely

questioned concerning his sexual morals. I do not know whether it is dread of the patient's displeasure or simply a want of appreciation of the frequency and potency of this genetic factor in the history of functional nasal disturbance, that leads to the omission of such inquiries, but will it be denied that they are the exception rather than the rule? The exercise of a little discrimination, of, perhaps, a little common sense, will protect a large proportion of our male patients from being subjected to an investigation of this nature, but in many others there will be fair reason to suspect moral laxity, and in these, there should be no hesitation in either confirming the suspicion or in taking the fault for granted and dealing with it frankly and vigorously.

Without having treated any great number of such cases, I have met with sufficient of them during the past few years to open my eyes to the fact that some early failures to effect in them decided and permanent improvement, were due to my failure to recognize and remove the principal cause of their annoying symptoms. A brief reference to the patient who first enlightened me on this point may be of interest.

He was a widower just turned 40, handsome, well-read, widely traveled; a man of most versatile cleverness, an excellent musician, something of an artist, and an occasional writer of very fair verse. All these merely personal details are distinctly relevant, because they are the very things which make a man *persona grata* to the other sex and which consequently expose him to greater temptations than his less attractive fellow. In such men, therefore, we may look much more confidently for easy virtue as an exciting cause of nasal trouble, than in those to whom nature has been less kind. This man recited a list of symptoms that was suggestive of enfeebled vasomotor control over the circulation of the pituitary membrane. There were brief intervals during which he was comparatively comfortable, but the greater part of the time he was seriously annoyed by nasal obstruction, by marked hypersecretion, by occasional paroxysms of sneezing, and by some dull frontal headache. An accompanying marginal blepharitis also testified to the intra-nasal irritation. His statement that he had already endured considerable treatment was amply confirmed by my rhinoscopic examination. His turbinates, both inferior and middle, presented an array of galvano-cautery cicatrices that reminded one of the scarred faces of the German duelists. This seemed to have been the favorite local treatment, but in addition, a fancied neurotic temperament had been assailed with many pills, a suspicion of gout had been threatened with drowning by gallons of lithia water, and, finally, some one had tapped both his antra through the inferior meati as a sort of forlorn hope. It was only a happy accident that saved me from the fate of my predecessors. A review of the treatment he had received yielded me little hope of finding anything of promise that had not already been tried. The end of a month of tentative local treatment, of regulation of diet, exercise, and some other matters of personal hygiene, found us but little beyond the point from which we had started. But just at this critical juncture when I could detect some slight signs of disappointment and failing confidence on the part of my patient, a bit of scandal came to my aid. It was the whisper of an intrigue in which my patient was playing the rôle of Juan. At our next interview this Lovelace admitted without any reluctance the habit-

ual looseness of his conduct with women. He made no attempt to conceal his amused incredulity when I charged this vice with being largely responsible for his nasal discomfort, but he agreed nevertheless to give virtue a month's trial. Not to rob this remedy of any possible credit, all other treatment was for the time suspended. Brief as it was, the period of probation proved more than sufficient to vindicate my faith in the prescription, and I was able to dismiss my patient with the assurance that his best safeguard against future return of this trouble, would be a rigid observance of the spirit as well as the letter of the Seventh Commandment. It is always my endeavor to be as sparing as possible in the use of drugs, but in cases such as this, where from long disuse, self-control has undergone a shameful enfeeblement, the bromids or any of the other anaphrodisiacs may be utilized to dull the vicious appetite, until sufficient will power is regained to completely conquer it.

DISCUSSION.

Dr. MACKENZIE The relationship between over-indulgence of the sexual powers and morbid conditions of the throat, eye and ear has been recognized from a very early period. The fact is about as old as literature itself, but the pathologic relation between the nose and the reproductive apparatus is a matter of recent recognition. The first attempt to reduce the subject to a scientific basis was made by me some fifteen or sixteen years ago, and I subsequently published the result of my observations in the *American Journal of Medical Sciences* for April, 1884. Subsequent observations made, among others, by Arviset, Ischwell and Joal in France and by Peyer, Endries and Fliess in Germany have only served to sustain the positions taken in my original essay. Fliess has written a very elaborate monograph on the subject. The phenomena observed furnishes food for reflection not only for the physiologist and pathologist, but also for the biologist. In contemplating them, we are brought face to face with a most interesting enigma—a problem of life whose biologic significance it must be the task of the future to divine. Dr. Grayson's cases furnish additional corroborative evidence of a most important physiologic relationship.

DIFFICULT DEFECACTION IN INFANTS.

Presented in the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

By THOS. CHAS. MARTIN, M.D.

Lecturer on Diseases of the Rectum in the Cleveland College of Physicians and Surgeons (Medical Department of the Ohio Wesleyan University), Surgeon for Diseases of the Rectum in the Cleveland General Hospital, Member of the American Medical Association, Member Ohio State Medical Society, Member Cleveland Medical Society, Member Cuyahoga County Medical Society, etc.

CLEVELAND, OHIO.

I should be unmindful of the history of human experience should I harbor the hope that the several affirmations set forth in this paper would be accepted without disagreement by a body of medical men. Remembering, however, that there is very little progress in knowledge except along lines where soundest casuists doubt, I propose for discussion the problem of difficult defecation in infants.

It is generally recognized that infants strain at stool.

The infant strains at stool because of the imperfect development of the anatomic features concerned in the mechanism of expulsion. These are as follows:

1. The infant's lower gut is muscularly deficient.
2. Its mobility within the abdomen is obstructive to defecation.
3. The rectal valves are obstructive.
4. The infant's anus not being sufficiently expansible is also obstructive.

The specimens of infant recta and sigmoid here

shown are the first taken in my research on this subject, and are fairly illustrative of the facts upon which the foregoing declarations are based. The large specimens examined are those of adults and are typical.

The dried specimens shown in plates 3, 5, 7, 9 and 20, were prepared by flushing the intestine and then fixing the subject in the genu-acromial posture; the anus was then fixed open and melted paraffin was injected under about twelve ounces pressure. When hardened that portion of the gut occupied by the cast was removed¹. Specimens shown in plates 11 and 12 were prepared by placing the subject in the dorsal decubitus and by opening the descending colon; the intestine below was then washed out and the colon perforation fixed at the abdominal wound, which save for this point was sewed up, the anus was tied up and as much melted paraffin as would enter under two pounds' pressure was forced into the gut; subsequently the sigmoid and rectum were removed as in the other cases. After immersion in alcohol the specimens were varnished.

The following are the memoranda of the autopsies made in this study:

Case 1.—Female, still-born; height 16 inches (40.64 cm.); circumference at anterior superior spinous process $7\frac{1}{2}$ inches (19.05 cm.); anterior superior spinous process diameter 3 inches (7.62 cm.); ensiform to pubes 4 inches (10.16 cm.); transverse diameter pelvic outlet $\frac{3}{4}$ inch (1.90 cm.); peritoneum at last vertebra of coccyx. (Plate 3.)

Case 2.—Female, age 1 hour, height 17 inches (43.18 cm.); circumference at anterior superior spinous process $7\frac{1}{2}$ inches (19.05 cm.); anterior superior spinous process diameter $2\frac{1}{2}$ inches (6.35 cm.); ensiform to pubes 4 inches (10.16 cm.); transverse diameter pelvic outlet $\frac{1}{2}$ inch (1.27 cm.); peritoneum at last vertebra of coccyx. (Plate 5.)

Case 3.—Male, age 1 month, height 23 inches (58.42 cm.); circumference at anterior superior spinous process 9 inches (22.86 cm.); anterior superior spinous process diameter $3\frac{1}{2}$ inches (8.89 cm.); ensiform to pubes 4 inches (10.16 cm.); transverse diameter pelvic outlet $\frac{5}{8}$ inch (1.59 cm.); peritoneum at last vertebra of coccyx.

Case 4.—Female, age 6 weeks, height 24 inches (60.96 cm.); circumference at anterior superior spinous process $10\frac{1}{2}$ inches (26.67 cm.); anterior superior spinous process diameter 3 inches (7.62 cm.); ensiform to pubes $5\frac{1}{2}$ inches (13.97 cm.); transverse diameter pelvic outlet $\frac{5}{8}$ inch (1.59 cm.); peritoneum at last vertebra of coccyx. (Plate 9.)

Case 5.—Female, age 2 months, height 20 inches (50.80 cm.); circumference at anterior superior spinous process 8 inches (20.32 cm.); anterior superior spinous process diameter 3 inches (7.62 cm.); ensiform to pubes $3\frac{1}{2}$ inches (8.89 cm.); transverse diameter pelvic outlet $\frac{3}{4}$ inch (1.90 cm.); peritoneum at last vertebra of coccyx. (Plate 20.)

Case 6.—Male, age 6 months, height 24 inches (60.96 cm.); circumference at anterior superior spinous process 10 inches (25.40 cm.); anterior superior spinous process diameter 4 inches (10.16 cm.); ensiform to pubes 5 inches (12.70 cm.); transverse diameter pelvic outlet $\frac{3}{4}$ inch (1.90 cm.); peritoneum at last sacral vertebra. (Plate 11.)

Case 7.—Male, age 6 months, height 24 inches (60.96 cm.); circumference at anterior superior spinous process 12 inches (30.48 cm.); anterior superior spinous process diameter 4 inches (10.16 cm.); ensiform to pubes 5 inches (12.70 cm.); transverse diameter pelvic outlet $\frac{3}{4}$ inch (1.90 cm.); peritoneum at first bone of coccyx. (Plate 12.)

Case 8.—Male, age 17 months, height 25 inches (63.50 cm.); circumference at anterior superior spinous process 12 inches (30.48 cm.); anterior superior spinous process diameter 4 inches (10.16 cm.); ensiform to pubes 6 inches (15.24 cm.); transverse diameter pelvic outlet 1 inch (2.54 cm.); peritoneum at last sacral vertebra. (Plate 7.)

Examination of the pictures of the dried specimens reveals that the wall of the infant rectum and sigmoid flexure is thin compared to that of the adult. (See plates 3, 5, 7, 9 and 20.) It is impossible to distin-

guish the longitudinal muscular bands which are so apparent in the gut of the adult. (See plates 1, 2, 17.) In the fresh state the mucous membrane constitutes a great part of the thickness of the gut wall of the infant, and the mucous membrane and muscular coats are more intimately adherent than in

the adult. The infant gut is very deficient in muscular elements, therefore the intrinsic power of peristalsis can not be present in that degree necessary to it as a component factor of defecation.

The relations of the peritoneum to the rectum of the infant, also contribute to the difficulties of defeca-

tion, as also does the relatively great length of the descending colon and sigmoid flexure.

In the child the mesentery of the sigmoid flexure and rectum is disadvantageously long. In young children the length of the sigmoidal mesentery from its attachment to the parietes to its invagination of the lower loop of the sigmoid is often greater than the

distance from the promontory of the sacrum to the distal bone of the coccyx. (See plates 13, 14.) From the sigmoido-rectal juncture to the beginning of the middle third of the rectum the mesentery rapidly shortens but apparently completely invests the upper third of the rectum. The middle and lower thirds are not so completely invested and present upon their

FIG. 13.—Side view of specimen shown in Fig. 12. The mesentery from sacrum and coccyx to the rectum is fairly well shown, but is shown shorter than in the fresh state, alcohol immersion, varnishing and drying having shrunk it. Observe also how nearly the peritoneum approaches to the anus.

FIG. 14.—The reverse of the view shown in Fig. 13.

FIG. 15.—Diagrammatic of this gut in the empty state, therefore its flexions are not the same as those shown in the photographs. In the partly filled state, which is the condition about the time of defecation, the flexions and positions of these parts would be intermediate to those of the filled and empty conditions. (The dotted lines indicate positions of valves.)

FIG. 16.—Diagrammatic, showing direction of forces and resistance in infant (A) and adult (B) and in defecation.

posterior parts a vertical lane bare of peritoneum, from the borders of which the peritoneum is reflected in lateral directions. This uncovered part of the gut is not applied directly to the sacrum and coccyx, and there is a space between which is occupied by loose connective tissue. The distance from the dorsal parietes to the gut is variable here, being from one-half to one-fourth of an inch (1.27 to .63 cm.) At the beginning of the middle third there is usually a gradual decrease in the length of the peritoneal band as it descends till it is one-eighth or possibly but one-sixteenth of an inch (.32 or .16 cm.) in length at the last bone of the coccyx; it rapidly shortens from this point to its termination. The parietal peritoneum descends over the ischial tuberosities and approaches nearly to the ental sphincter muscle. In the newly born the peritoneum is situated within one-fourth inch (.63 cm.) of the anal skin. (Observe plate 13.)

FIG. 17.—Photograph of a female cadaver showing, after laparotomy and removal of bladder, uterus and adnexa, the upper rectum and sigmoid packed with scybala; ss, symphysis pubis; la, ligature at anus. The shorter mesentery of the adult, perhaps, keeps the greater portion of the sigmoid flexure above the ileo-pectineal line that it may not escape the auxiliary forces of defecation. It is noticed that the sigmoid is more than normally distended. Quarter life size.

The disproportionate great length of descending colon and mesentery of the infant obviously contributes to the possibility of angulation of the gut.

We see in the presence in the child of lax and long, or relatively long, peritoneal ligaments, and in the great length of the descending colon and the consequent probability of numerous acute angulations in the infant sigmoid and rectum, and in the mobility of these parts within the abdomen, the possibility of development of a perfect adult mechanism for defecation. The essential features of this development are two; first, the growth of prostate or uterus and their supports which fix the lower rectum: and second, the down-growth and out-growth of the pelvic bones and the consequent conversion of mesenteric peritoneum to parietal peritoneum, which shortens the adult mesentery and in great measure fixes the upper rectum; thus the entire rectum is steadied to facilitate discharge when the mechanism of defecation is set in operation.

The diagrammatic plate 15 does not exaggerate these obstructive elements. The collateral muscles which assist in the performance of the act of defecation force the feces in the direction of the lower angle in each flexion, and in that flexion whose onward, or to be paradoxical, whose downward direction for the time

points upward (plate 15), the auxiliary pressure is in the direction opposite to that of peristalsis.

Inspection of the pictures of the dried specimens reveals the angulations referred to, which may be expected to be more numerous the more segmentary the gut's contents.

The third feature obstructive to defecation in infants is the rectal valve. It is a feature and factor which not only is not recognized, but is one whose very anatomic existence has been most ingeniously and persistently disputed. It was imperfectly described as an anatomic feature of the rectum by Mr. Houston in the Dublin Hospital Reports in 1830, and many years later Dr. Walter A. Otis (1887) more practically demonstrated its presence; neither of these gentlemen, however, attributed to it the characteristic element of an anatomic valve, although bestowing upon it its proper name. A number of investigators have discovered

FIG. 18.—Interior view of the left half of the rectum of an adult. Filled in the procto-colonoscopy posture, and distended only to the degree of normal atmospheric inflation. The anus is at the left of the picture. The valves are respectively two and one-half and seven inches (6.35 and 17.78 cm.) from the anus. One-half life size.

this normal contracture of the ampulla and have mis-called it by various names and given it widely varying descriptions; but a greater number still deny its existence and critically strive to dissolve away the imperfect evidence recorded in medical literature².

The pictures here shown of the dried specimens prove that in the infant the valve is such a matter of fact that its existence is no longer a matter for debate.

In each and every instance of more than three hundred persons examined by me these valves have been present, though in varying number and position in different subjects³. In most cases there are present three valves, in some there are four and in others there are but two.

I have marked that by some law of compensation

² See Monograph by the writer on New Evidence that the Rectal Valve is an Anatomical Fact, John P. Norton and Company, Louisville.
³ See paper by the writer, Procto colonoscopy, etc., Mathew's Quarterly Journal of Rectal and Gastro-intestinal Diseases, July, 1896.

the fewer the number of valves in a given subject the better are they developed.

The infant specimens shown indicate that the valves are particularly well developed at birth. The specimen shown in plate 20 is marked by two valves in the so-called ampullar region, situated so close together that the middle portion of the rectum presents its longest diameter at right angles to the main direction of the gut. Another valve may be seen at the juncture of the upper portion and the sigmoid flexure.

The specimen shown in plate 18 is that of an adult, and presents two valves on the left and one on the right which is not exhibited. As these valves usually span more than half the circumference of the rectum it will be understood that in specifying their situation I refer to their central part. In many cases they are situated on the anterior and posterior walls, and their free borders are always directed a little obliquely, contributing a spiral direction to the channel of the rectum. The depth of the valve from free border to the

FIG. 19.—The rectum the same as is shown in Fig. 17, divided into anterior and posterior halves. Amp., anal end of ampulla; ss, sigmoido-rectal communication; xx, x's, a semilunar valve dividing the middle and upper portions of the rectum; m, the beginning of a semilunar valve on the right of the posterior wall, and m'm', the same valve continued over the anterior wall; h h, a small valve not prominent because of the empty state of the gut at this point; b b, sigmoido-rectal valve; n, a portion of mesentery. One-half life size.

border attached, is usually about one-third the transverse diameter of the inflated rectum, and the valve is about one inch (2.54 cm.) in depth at its deepest point. Inspection of the photograph of the adult specimen (shown in plate 19) which was taken from the subject without disturbing its scybalous contents, shows that the valve may be found in systole (*vide* xx, x's) or diastole (*vide* m, m'm').

The microscopic section which is here shown was taken from the middle of the lower valve of the adult specimen. (Plate 18.) In the illustration (plate 18) it is shown magnified fifteen diameters. The thickened state of the mucous membrane over the free border of the valve fortifies that point against the increased friction which that part must necessarily bear. Beneath it is noticeable the heavy layer of fibrous tissue which gradually diminishes till it is lost at the valve base. Bundles of circular muscular fibers are seen in the middle of the valve. At its base are seen arteries and veins for its special nutrition. This structural arrangement makes this organ the typical anatomic valve.

Speaking with anatomic accuracy the rectum is divided into as many portions, plus one, as there are valves in the rectal ampulla; for example, the rectal ampulla may be said to begin just below the angle which marks the termination of the sigmoid flexure. If there be two valves below this point, that part of the rectum above the higher one of these two valves must be considered the upper or first portion of the rectum, that part below the higher valve and extending to the lower, the middle or second portion, and that part of the rectum below the lower valve and terminating at the levator ani may be called the lower or third portion. Should a rectum have three valves, or perhaps but one, not counting the one at the sigmoido-rectal juncture, that subject's rectum accordingly should be considered to have four or two portions. Therefore if we recognize the existence of these valves in the rectum the conventional division into upper, middle and lower thirds, which is employed by the anatomists should be abandoned.

FIG. 20.—The rectum and sigmoid of an infant aged two months. The photograph shows the interior of the anterior half. Portions of two valves are noticed at the middle part.

It must be readily seen that the presence in the rectum of such a structure as an anatomic valve would be essentially obstructive to the passage of feces.

In studying the physics of the rectum it is important that we recognize that the posterior wall from which the mesentery is reflected is less movable than other parts in the circumference, hence distention of the rectum not only tends to carry a given point of its wall away from a point opposite to it, but also carries it away from a given point cephalad or caudad. So it may be assumed that if the two valves situated at the ampullar middle of the cast-distended dried specimen (plate 20) are three-eighths of an inch (.95 cm.) separated, and that the two opposite walls of the rectum in the portion bounded by these valves are one inch (2.54 cm.) apart, that in a state of the gut's collapse or systole, the valves would be in contact, and thus afford a very definite obstruction to the descent of semi-solid feces.

The bony pelvic outlet in the infant is so contracted that the limits of anal expansion are such as to almost defeat the passage through it of other than fluid feces. It should be remembered that the normal average measurement from ischial tuberosity to ischial tuber-

osity in the adult is about four inches (10.16 cm.), and it is a fact proven by our observation that the average transverse diameter of the newly-born infant's pelvic outlet is but a little more than one-half inch (1.27 cm.), the pubo-coccygeal measurement is even less. Those who are familiar with instrumental divulsion of the adult anus have observed that two and a quarter inches (6.35 cm.) is the average limit of lateral separation of the anus, the remaining portion of

compared to the adult the juxtaposition of the ischial tuberosities in the infant supplies a most obstinate obstructive factor in defecation.

To collate in brief:

1. The muscular development of the adult rectum and lower sigmoid is plainly apparent in the plates here exhibited of the fresh specimens. A deficient muscularity is observed in the infant specimens.

2. The peritoneum of these parts in the adult is observed to be relatively, very considerably shorter than that in the infant¹.

3. The rectal valves appear to bear the same proportion to the gut in both adult and infant, but when we remember the difference in muscular development in the two the disproportionate resistance of the valve in the infant rectum is obvious.

4. The anal expansibility is remembered as adequate in the adult, and is seen to be deficient in the infant.

Co-relative to the facts just stated we must recognize that the adult rectum has resident within its own wall a powerful expulsive muscular mechanism; that the shortening of the mesentery holds the upper rectum

FIG. 21.—The interior view of the opposite posterior half of the rectum shown in Fig. 20, the two valves shown in Fig. 20 being continued toward each extremity of the ampulla. The sigmoid is out of focus.

the bony outlet being filled with the compressed soft tissues of the ischio rectal space. Therefore it may be estimated that nine-sixteenths at most, of the diameter of the pelvic outlet is the reasonable limit of expansibility of the anus for the passage of feces. Applying this calculation to the infant we find that if the ischial tuberosities are one-half inch (1.27 cm.) separated, that the anal expansibility is but five-six-

teenths under the applied auxiliary forces; that the angulations of the sigmoid are not necessarily obstructive, though in a desirable measure retardative; that the forward incline of the lower sacrum and coccyx behind, and the development of the uterus and prostate and their inherent supports in front, provide the lower adult rectum with a firm funnel-like arrangement which guides the feces directly upon the os internum of the anus; that the valves divide the feces into portions to facilitate their separate successive discharge, and finally in sequence, that the physiologic descent² of the structures of the ischio-rectal space reduces this last resistance to the minimum in adult defecation.

Straining, the ruptures and prolapses, constipation,

FIG. 22.—The paraffin cast removed from the gut pictured in Figs. 20 and 21.

teenths of an inch (.79 cm.), which is, as we know, the diameter of a No. twenty-two sound (French scale). Reference to the paraffin cast of the infant gut (plate 22) indicates that the average distensibility of the sigmoid flexure and rectal ampulla, in which the feces when firm are formed, is four or five times that of the anal expansibility; thus it is readily perceived that

¹ See Andrews' Surgery of the Rectum, table of peritoneal relations to adult rectum.

² Chadwick Transactions American Gynecological Society, 1877.

retention of feces and the multitudinous consequent ills have demanded our patient inquisitive consideration; and this study forces the conclusion, I believe, that the individual's escape is ultimately assured by process of development, but that for the normally formed infant, the physician will find the solution of the problem of difficult defecation in the solution of the stool.

1077 Prospect Street.

MEDICINE AND THE STATE.

From a paper read before the Contemporary Club, Davenport, Iowa, Nov. 18, 1897.

BY C. H. PRESTON, A. M., M. D.
DAVENPORT, IOWA.

Just half a century has passed since, in 1847, Liverpool, and soon after, London—fearing a cholera invasion—appointed the first medical officers of health in Great Britain.¹ The next year, the dread scourge having made its appearance, a central board was established, and today, to quote Palmberg's *Public Health*: "Of all the countries of the civilized world none has a sanitary code so complete and so precise as England." That its provisions are respected by all and, as a rule, religiously observed, he rightly ascribes to the fact that they are the work of the people themselves and not mere administrative orders but little understood.

The sanitary administration of England is placed, in accordance with the public health act of 1875, in the hands of a government board acting together with boards locally established. The former consists of a president appointed by the crown, a parliamentary and a permanent secretary, together with various secretaries and high officials of state acting as advisory members. Its work is divided among the general departments of poor-law administration, the sanitary regulation of buildings, of factories, of sewers and streets, water supply, vaccination and other matters pertaining to public health.

Complete as is its present organization however, there is a movement now on foot to place it on a yet higher plane.² A motion will soon be made in Parliament, it is said, that "in the opinion of the House of Commons it is desirable that a department of public health be constituted and that the same be under the charge of a responsible minister having a seat in Parliament."

In this country the first step in state medicine was taken in 1849, when a commission was appointed by the governor of Massachusetts to prepare for a sanitary survey of that State.³ But the Massachusetts State Board of Health, the first active State board to be formed in the Union, was not established until 1869. Meanwhile, in 1865, the State of Louisiana, in order the better to cope with an invasion of yellow fever, had appointed what was actually the first State board, though it possessed but very limited powers. At the present time all but ten of our fifty-one Federal divisions, including the District of Columbia, have each its more or less active board of health, all working together for the general welfare, while local boards under them, everywhere co-operate for the sanitation of cities and towns.⁴ The ten exceptions are Alaska, Arizona and the Indian Territory, Georgia, Idaho, Montana, Oregon, Texas, Utah and Wyoming. Georgia formerly possessed a State Board, but allowed it to lapse for lack of an appropriation. Texas, though without a State Board, maintains a State Officer of Health.

But the United States has today no national board or department of health. The first step was indeed taken toward the nationalization of health in this country March 3, 1879, when an act of Congress to prevent the introduction of contagious or infectious diseases and to establish a national board of health was approved.⁵ The board thus authorized, however, had but four years of active existence. It consisted of eleven members, seven appointed by the President and one each detailed from the Medical Department of the Army, the Medical Department of the Navy, the Marine-Hospital Service and the Department of Justice. It had no definite term of office and its duties, beyond gathering and disseminating information, were advisory merely. An act approved June 2 of the same year somewhat extended its powers but was limited to the four years succeeding, at the end of which period—Congress refusing to re-enact—the board ceased practically to exist and the act establishing it was at length formally repealed Feb. 15, 1893.

The place of a national board is now filled in part by the Marine-Hospital Service, a bureau of the Treasury Department, aided by the Bureau of Animal Industry of the Agricultural Department.

The Marine-Hospital Service was established in 1798, but placed on its present basis in 1871.⁶ Its purpose was to care for the sick and disabled seamen of the merchant marine. In default of a national department of health, however, other duties and responsibilities have from time to time devolved upon it, giving it an anomalous position in the government, without definite scope or determinate power. The Revenue and Life-Saving Services depend upon it for the physical examination of their officers and men: it assists the Steamvessels Inspection Service by examining pilots for color-blindness; it is entrusted with the execution of the national quarantine laws, the management of the eleven national and the inspection of all local quarantine stations and with power to enforce inter-state quarantine regulations; it investigates reported cases of epidemic disease, collects and disseminates mortality statistics and sanitary information and makes investigations (bacteriologic, etc.) into the causes of disease; it examines immigrants for the existence of contagious diseases and has service in consul's offices at foreign ports to secure accuracy of bills of health given.⁷

The Bureau of Animal Industry investigates as to the existence of communicable diseases of stock, superintends measures for their extirpation and pursues investigations as to their nature and means of prevention. It has charge of the inspection of import and export cattle, vessels of export and stock quarantine stations, and supervises the inter-state movements of live stock and their slaughtered products.⁸

But when all is said, both bureaus remain and must remain subordinate organizations, subservient in part to other interests than those of health.

Another organization which has done and is doing much to promote and harmonize sanitary work in and between the States is the American Public Health Association, a body composed of the leading sanitarians of the United States, Canada and Mexico. But it is wholly without government authority or support.

The need for a sanitary head with which other nations could confer and co-operate authoritatively and promptly, which should co-ordinate, supplement and assist, but in no way supplant the several State boards, has long been felt; and various bills for estab-

lishing such a head, mostly crude and imperfect, have from time to time been introduced in Congress. In the closing hour of the last meeting of the AMERICAN MEDICAL ASSOCIATION a committee, appointed in 1891 to consider and report on this subject, brought in and recommended the most complete bill yet offered.⁹ It was approved and they were instructed to present it before Congress at their discretion and to urge its adoption. The bill, as formulated, provides at much length for the establishment of a department of health which shall succeed to the present sanitary duties and powers of the Marine-Hospital Service, and of which the latter shall constitute a subordinate bureau, continuing its appropriate work. But by this bill the head of the new department is made a commissioner merely and not, as was the original intent of the ASSOCIATION, a secretary and one of the President's cabinet advisers.

Such is the existing status. Let us turn now to a consideration of some of the work waiting to be done by a department of health when it shall be established.

Our yellow fever epidemic of the past season, with its needless sacrifice of life and its prolonged interference with business interests—the latter costing the city of New Orleans alone, as estimated by the *New York Herald*, over \$25,000,000¹⁰—forcibly illustrates the importance of greater national quarantine powers in dealing with incipient epidemics, which may well develop into national calamity.

Quarantine measures had their beginning in the twelfth century, when the Republic of Venice, after suffering repeated devastations by cholera, sought thus to protect itself against infected Asiatic ports,¹¹ and from that time they have held a first place in national sanitation. But to be effective, quarantine must be prompt and inclusive, must be broadly national in its scope. No local interest must have power to prevent or delay.

Another most important field, but partially occupied at present, is that of biologic research. Carried on to some extent, as we have seen, in and for the Bureau of Animal Industry and the Marine Hospital Service, it should be greatly extended for the investigation of human bacterial diseases.

Vital statistics, too, if collected under organized medical control, could be extended to cover much more fully than at present questions of disease distribution, with regional influence, etc., and above all be given a degree of accuracy and uniformity which, though essential to their working value, it is not now possible to attain. By present census methods the apparent death rate of the United States in 1890 was but 13.98 per 1000 of living population, whereas the actual rate, as estimated by the census commissioner himself, is about 18 per 1000, showing how unreliable are the data from which it was attained.

The registration States, in which alone there is any approach to accuracy of enumeration of births, marriages and deaths, comprise only about 4 per cent of the area, with one-fifth of the population, of the Union. Registration should be provided for in every State; there should be a trained census service permanently established, and the present too long decennial period should be cut in two. Commissioner Wright is seeking to effect these reforms; with a department of health they would be naturally attained.

In the care of the defective classes, and in measures to eventually reduce their numbers, the depart-

ment could greatly aid—at least through co-ordinating—State and municipal effort.

There were in the United States, June 1, 1890, according to the eleventh census, 106,254 insane, 95,571 feeble-minded, 121,178 deaf and deaf mutes, 144,399 blind and 194,027 sick and disabled (in the registration States); in all 661,429, or over 1 per cent. of the entire population. This means a vast loss, both in productive power and in cost of care, a loss which ought to be greatly reduced. It must be allowed that from a purely economic standpoint, the care of defectives is a very pertinent affair of State.

We may not be prepared to agree with the Colorado philanthropist who advocates "the judicial taking-off" of the incurable insane, though such a procedure would seem to accord both with justice to the taxed producer and with the spirit of the golden rule; but it may surely be questioned if favoring the defective, to the ultimate lowering of racial vitality, is wise. Rather let us seek to increase productive strength and the expectancy of life through concerted measures to prevent disease and remove the causes of defect.

"The state of the future," says Jacobi (*Therapeutics of Infancy and Childhood*), "will have to see to it that epileptics are not placed in a position to raise progeny equally accursed. . . . The daughters of hemophilic families ought not to be allowed to marry."

Society and the state, with its organization of ignorance and disorder, are responsible for so much of deaf-mutism as is not pathologic. . . . The individual should be controlled by the community in the interest of the public health."¹²

Dr. Toulouse, a French writer on mental diseases, would have the existence of either epilepsy, cancer, syphilis, tuberculosis, or alcoholism bar legal marriage.¹³ The Connecticut legislature has, I believe, passed an act prohibiting the marriage of epileptics, and a progressive member of the Texas legislature has formulated a bill requiring of each party to a proposed marriage contract, a certificate of physical soundness from some competent physician, together with the applicant's sworn statement of his freedom from any transmissible disease.

I quote these propositions, not as practicable of direct application, but as indications of a trend of earnest thought. Education in this direction is to be desired and furthered, but prohibitive marriage regulations, beyond those already in force as to consanguinity and incompetency (from whatever cause) to contract, would doubtless result in more harm than good by increasing the number of illegitimate births.

Another work of importance to the Nation, as well as to the several States, is the regulation of medical practice, fixing the qualifications of those to be entrusted with the citizen's life and health.

Under the Justinian code or civil law, and under the common law no barriers whatever were raised. Any one might practice either medicine or law, regardless of fitness or qualification (but subject always for injuries inflicted on others), the right of choosing an occupation being held to be inherent. But the tendency of legislation is to prescribe qualifications for practice, an exercise of the public power justified by regard for the welfare of the people, which is the supreme law. The right to practice (subject to reasonable qualifications) is neither a property right nor a vested right, but is a right, nevertheless, which can not be arbitrarily taken away. Such in substance is the opinion of Judge Pugh of Ohio, given in support of

the constitutionality of the Medical Practice Act of that State.¹⁴

All the States and Territories today, with the single exception of Alaska,¹⁵ recognizing the need for restrictive legislation, have medical practice acts, more or less stringent in force, but they are far from uniform in requirement or in enforcement. Of them all none, I believe, is more efficient than the revised Iowa law as enacted last spring. Its just requirements now apply, virtually without exception, to all who profess to heal or cure in any way whatever, by medicine, appliance or method, and if enforced must prove effective against ignorance and pretense. The State in its requirements can, of course, take no account of school or belief, but of knowledge and fitness only. These, however, it must require of all alike, with neither exception nor favor.

The so-called osteopaths, in their recent concerted raid for exemption, were happily, in this State, unsuccessful; but Michigan acceded to their ridiculous demand, Missouri had already done so, and Illinois was only saved from a like disgrace by the veto of her governor. A National department co-operating with all the States would strengthen each against legislative corruption such as was undoubtedly brought to bear in this case.

A field of work closely related to regulation of practice, and one in which the influence of a department might be exerted to advantage, is the supervision of medical schools. The report of the commissioner of education for 1894-5 shows the existence of 151 medical schools in the Union, or an average of more than three for each State, and more than twice the whole number of law schools existing, while the number of medical students (22,887) exceeds that of all law, theological and dental students combined.

There is, I believe, no legitimate demand for more than one-third this number of schools—doubtless a score, well equipped, would be all sufficient—and half the crowd of graduates annually set adrift would more than suffice for all actual needs.

There is reason to hope that the near future will witness a much to be desired reform in this direction, whether or not it shall be hastened by the establishment of a department of health. Increasing State requirements and cost of medical education, says the commissioner in effect, seem to indicate the approach of a time when medical schools, outside the great population centers, will be rare; also increasing endowments point toward the establishment of more worthy foundations, which will eventually do away with the horde of joint-stock, medical advertising institutions, whose only reason for being is to advance the selfish interests of their professors.

But the State, it would seem, might well interfere more directly to this end. Its right to determine the fitness of the physician is unquestioned. Should not the qualifications of the professor be equally guarded? The public interest suffers much by our present laxity in this regard. Harm results not alone through the graduation of innumerable incompetents, but also by the induced life-failure of many youths of good parts who, with little natural adaptation for the physician's life, are lured to a fatal expenditure of time and money, drawn into the clamorous portals of a profession from which they should rather have been kindly turned aside. In medicine especially is it true, as tersely expressed by an eminent scholar, that "we are constantly making the mistake of training men out

of their capacities." The student should be met at the outset with careful tests, supplemented by kind and disinterested advice as to the choosing of his life career.

Another matter calling urgently for supervision is the manufacture of the various potent animal products to which the rapid growth of so-called serum-therapy is constantly giving rise. The many tuberculins, antitoxins, etc., in the market have each its dangerous as well as its beneficent possibilities. As an immunizing agent, representing the entire class, we may take vaccine production alone. If it is ever the duty of the State to require vaccination—and its protective power is overwhelmingly proven—it is at the same time unquestionably her duty to see to it that the virus employed is pure. At present this is not done. "In most States," says Dr. Lindsley, secretary of the Connecticut State Board of Health, "there is no legalized supervision."¹⁶ Dr. Pittfield, reporting to the Pennsylvania State Board, after a careful examination of a large number of vaccine-producing establishments finds "great carelessness and negligence as to the purity of the product," with "no official supervision" existing.¹⁷ And Dr. Abbott of the Massachusetts State Board, replying to an inquiry from the president of the Medico-Legal Congress of last year, meeting in New York, says: "Very little supervision is exercised in this country over the production of vaccine lymph," and expresses the opinion that its production "should be under the supervision of either State or National authorities."¹⁸ This and other like products of incalculable sanitary importance, are widely distributed without regard to State lines, and the need for their National control, it would seem, must be plainly apparent; as also for control of the flood of patent and proprietary medicines, whose least evil is their immense money cost.

Of all sanitary measures requiring powers more extended than those of the several State boards, none is more important, perhaps, than the prevention of the pollution of streams. But here it may be objected, in the words of Dr. Billings, that: "The general Government can do little in the way of compulsory legislation which might interfere with the action of the several States to control their own sanitary affairs."¹⁹ If this be true then greater power must be obtained through constitutional amendment, awaiting which the exercise of the right of eminent domain would find in so important a public need its most complete justification.

A subject to which I can but allude is that of National interest in endemic affections. In dealing with diseases so threatening to racial vitality as are leprosy, syphilis, and above all tuberculosis, there is need for the active aid of a department having National jurisdiction and powers. Consumption, according to Koch, is responsible for one death in seven the world over; one in eight and one-sixteenth by our own census of 1890; and owing to its principal methods of transmission, linked as they are with food-supply and means of transit, local measures are inadequate to its effective control. The danger from tuberculous meat and milk, and from the dissemination of tuberculous sputa, is now generally admitted, but in not more than one-third of the States, and in about the same proportion of the larger cities of the Union, are any practical measures being taken to meet it.²⁰ The movements of tuberculous cattle and their food products need Federal power for their prevention;

in the oxydation of the alcohol. Claude Bernard failed to take up Prof. Ford's line of study, from the supposition that the vinous fermentation is the work of the torula cervisiæ solely and from knowledge that this ferment does not exist in the animal economy. Prof. Ford's experiments show that liver-tissue will induce alcoholic fermentation in diabetic urine, and that decoction of liver-substance undergoes this process within a few hours at 100 degrees to 106 degrees F., but not at 60 degrees; hence he concludes that the liver furnishes the ferment. So far as I know, this line of investigation has not been pursued by others, but the work was done with utmost care by a competent expert, and the conclusions are entirely reasonable.

Pavy, in common with most observers, found that alcohol, moderately taken, increases both rapidity and fulness of the pulse. Very little effect is produced upon the temperature of a healthy person, or upon the elimination of nitrogen, by a small amount, according to Dr. Parkes; and he thinks it unlikely that a person can thereby perform more work on less food, though, by stimulating a failing heart, it might enable one to put forth an effort otherwise impossible.

Authorities differ about the comparative exhalation of CO₂, with and without ingestion of alcohol, and it is evident that there is no material difference. Competent and unprejudiced observers generally agree that a small quantity of fermented liquor or diluted spirit promotes the digestion of substantial food, especially of a fatty nature. Sweet wines and malt liquors promote nutrition, through the sugar and extractive matters which they contain, but are apt to be followed by indigestion, headache and gout, from the plethora induced.

The experiments of Dujardin-Baumetz on pigs showed that no pathologic changes follow the daily ingestion of ethylic alcohol at the rate of one grain to 1 kilogram of body-weight, when taken diluted at intervals. He and B. W. Richardson set the same limit to daily assimilation of alcohol by a healthy human adult, without disturbance to digestion or other injurious consequence. This, for a person weighing 150 pounds, would amount to 71 c. c. of absolute alcohol, or about 148 c. c. of brandy, whisky or rum, or 710 c. c. of claret—much more than a careful and intelligent person would choose to take. Even Anstie's limit of 59 c. c. daily of absolute alcohol would, in my judgment, be better divided by four, and then be taken largely diluted along with the two principal meals.

The effect of alcohol in large quantities is first excessive stimulation of the gastric capillaries and secreting follicles, followed soon by corresponding sedation, and by gastric catarrh, if often repeated. Strong spirits cause constriction by robbing the capillaries of water, diminish the flow of gastric juice, render the albuminoids less soluble, and seriously impair digestion. Taken in excess, alcohol can only be partially oxydized before reaching the liver, and in this organ the secreting cells are contracted by withdrawal of water from the capillaries, while the connective tissue is hypertrophied through stimulation. The eventual result is general contraction of the gland at expense of the secreting structure, and abdominal dropsy by pressure on the hepatic veins. Similar effects are produced upon the kidneys, but more slowly, as they are more distant from the stomach.

On the nervous system the effect of a small quantity of dilute alcohol is stimulation, with little or no reactive sedation. As the quantity is increased, especially if concentrated and taken on an empty stomach, the primary stimulation is shortened and the sedation magnified and prolonged. Intoxication may vary from maniacal delirium to profound stupor, and in either case the proper nutritive functions are proportionally disordered. Repeated excesses of this kind result in fatty degeneration of the nervous centers and softening of the arterial tunics.

There is no want of agreement among physiologists about the effects of excess in the use of alcoholic beverages, and no need of dilating upon this branch of the subject. It is now in order to notice the opinions of those who advocate total abstinence as the rule for all mankind.

Prof. N. S. Davis holds that both the carbonaceous and the nitrogenous elements of food contribute to tissue-growth and repair, and that animal heat results from molecular changes constantly taking place; while alcohol rather retards than promotes these processes, as shown by diminished body-temperature and elimination of CO₂. He asserts that alcohol has a greater affinity for the hemoglobin and serum of the blood than for oxygen, and consequently is not oxydized, so as to generate force in the forms of animal heat and muscular action. Undoubtedly the first demand of alcohol is for water, but this is not all. When taken in any reasonable quantity, it does not remain alcohol, nor in any case is it all eliminated from the body as such. Most of it is oxydized, and thereby its potential energy is developed into sensible force.

Dr. H. D. Didama of Syracuse, N. Y., asserts: 1, Alcohol is not food; 2, does not promote digestion; 3, does cause gastric disturbances; 4, does not increase muscular strength nor promote physical or mental endurance. Like other teetotalers, he does not distinguish between moderation and excess. The above assertions are true in excess, but not in moderation suitable to the individual case. Excess in any instance is more than suffices for gentle stimulation of the digestive and nutritive functions. Any degree of nervous derangement, whether mental excitement or torpor or muscular incoördination, means excess, from circulation of unchanged alcohol in the blood. He adduces the testimony of army and railway officers, Arctic explorers and trainers for athletic contests, that total abstainers bear extremes of heat and cold, sharp conflicts, long marches, exposure to storms and malarial infections better, and recover from fatigue and illness more speedily and thoroughly, than those who bounteously or sparingly partake of the flowing bowl. It is to be observed that he speaks of persons of full bodily vigor, amply supplied with good food, who do not need stimulation at all, and who could not be trusted to keep within the bounds of strict moderation. It is true that the rule of total abstinence is usually enforced in such cases, and the prudence of this course is admitted. On the other hand, there is evidence that a small amount of diluted alcohol will enable one to put forth increased mental and physical exertion for an emergency, to withstand cold with less suffering and recover from fatigue or prostration more quickly. Testimony to this effect is adduced and credited by the late Dr. W. B. Carpenter, in his excellent monograph on Alcoholic

Liquors. The difficulty is to keep within suitable limits. Most persons consider themselves qualified to judge for themselves in the use of alcohol, while they take medicines by the advice of physicians; and physicians themselves are no more prudent than the laity in their use of liquors. The explanation is, the appetite, rather than sound reason, is allowed to govern.

Dr. Charles H. Shepard² holds that the sense of well-being after taking alcohol is due to its benumbing influence; that its supposed building-up action is only an irritation from an effort of the system to get rid of the drug; that it exhausts vitality thereby more quickly, and therefore ought to be regarded as a poison. In support of the last conclusion he quotes Dr. Forel of the University of Zurich: "Alcohol, even when diluted, as in wine, beer and cider, is a poison which changes pathologically the tissues of the body and leads to fatty degeneration." Dr. Shepard adds: "Tea and coffee also belong to the same category of irritant drugs, which, by rousing the vital forces to get rid of the poison, provoke the action which is mistakenly supposed to be an added force, whereas the action is only one of self-preservation. Quinin is essentially nerve-poison and capable of producing a profound disturbance of the nervous centers." Dr. Shepard's consistency in adding tea, coffee and quinin to his list of poisons is incomplete without including the numerous condiments used in the preparation of food, with the exception of common salt, which alone can be regarded as a reconstructive constituent. They promote alimentation by rendering food more palatable and digestible; but they are injurious, when used to excess, as well as tea, coffee and alcohol. Shall they all be classed as poisons and be banished from our dietary?

Dr. I. N. Quimby thus discourses³: "What physician would be so bold or hazardous at this time, as to assert that the use of alcohol, even in a moderate way, did not have a tendency to produce various affections, such as congestion, ulceration and thickening of the gastric mucous membrane of the stomach, which did not in its turn produce indigestion, mal-nutrition and mal-assimilation, the result of which would have a tendency to produce disease of the kidneys, pernicious anemia, cirrhosis of the liver, fatty degeneration of the heart, tubercular disease of the lungs, cerebro-spinal irritation, with softening and lessening of the resisting power of the red corpuscles of the blood, producing various affections of the respiratory, digestive and nervous systems? It is stated by Dr. Nordau, the famous writer and philosopher, who combines scientific knowledge and literary power and originality of thought, that there is going on a general degeneration of the race. And who is bold enough at this period of the world's history, to successfully deny or refute it?"

This alleged degeneracy of the race has been going on since Noah planted the vine and got drunk on its product, on coming out of the ark; yet, within the period of profane history, the span of human life has doubled and is increasing. France, Spain and Italy are producing annually, according to different estimates, fifteen to forty gallons of wine *per capita*, most of which is consumed at home, and this has continued for centuries; while the output of wine and beer in Austro-Hungary is about fifteen gallons annually *per capita*, and double this amount in the German em-

pire. On an alcoholic basis, degeneracy in the latter progresses twice as fast as in the former. In these European countries children drink fermented liquors from the time they are weaned and follow the habit all their lives. Inasmuch as human life is steadily lengthening, popular education extending and military power growing, the present writer fails to see proofs of degeneracy.

Let us now view the alcohol question in the light of the doctrine of evolution. The most efficient factor in the elevation of all forms of life is survival of the fittest, from gradually acquired conformity with environment, whereby they grow to maturity and leave progeny endowed with increased faculty. At present the most destructive enemies of human life are the zymotic diseases, alcohol and narcotics. Proof abounds that the longer races have been subjected to these agencies, the less disastrous are the results. On the other hand, races newly exposed to them are immensely depopulated. Examples are found in the destruction of our aborigines by small-pox and alcohol. But the native population of Old and New Mexico, having been subjected to small-pox, with little or no modification by vaccination, for three and a half centuries, has acquired great tolerance and now suffers a low mortality. The races of tropical America have become so tolerant of yellow fever that total immunity is claimed for them by some writers, though on insufficient grounds. Syphilis has become much milder among the white populations of Europe and America during the last four centuries. The same is true of leprosy in India and China during unknown ages, in contrast with its recent invasion of the Hawaiian islands. The growing abuse of narcotics by the white races of Europe and America is contrasted by their moderate and almost harmless use in Hindostan, gained by centuries of habit. The general and intense craving for alcohol, so marked among the dark races of America, has mainly died out among those which have cultivated the vine for many centuries along the northern shores of the Mediterranean, by survival of progenitors who were temperate but not abstinent.

Even teetotalers allow that the worst effects of alcohol are produced by strong liquors, especially when taken on an empty stomach. Within the last twenty years the per capita consumption of malt liquors in our country has increased, while that of spirits has declined, and gross drunkenness has diminished. On the other hand, the consumption of spirits has greatly increased in France and that of wine diminished, since the ravages of vine-pests have seriously diminished the production of wine. Reasonable persons must agree that the changes are favorable to our country and the reverse to France. Another notable observation is the increasing use of such anesthetics as chloral, cocain, opium and its derivatives and the various coal-tar derivatives, especially where the traffic in alcoholic liquors has been most opposed by public opinion and legislation. There is a natural, and for many an irresistible, craving for some form of anesthetic, and it is reasonable to allow use of the least injurious, under suitable and practicable restrictions. Evidence abounds that the use of light red wines at the table is least injurious to average persons, and positively beneficial to most of the aged and debilitated, when taken in such moderation as to produce no appreciable effect upon the nervous system by excitement or stupor. Such use of alcohol would forestall

resort to anesthetic drugs, which seriously impair nutrition and ability for industrial pursuits.

For such persons as can not restrict themselves to moderate limits, who habitually use enough to effect perceptibly the nervous system, or who indulge in debaucheries which unfit them for business, there is no safety but in total abstinence. Likewise there are individuals who can not use tobacco, tea or coffee in moderation, and others who are extremely susceptible to their poisonous effects; and these too must abstain. It would be wrong to condemn all to deprivation because a few indulge to their detriment, and so far legislation has not been invoked to repress their use. It is proper to distinguish between excess in these and excess in alcoholic beverages, because the latter is more prevalent and harmful.

In the writer's judgment, it would be wise for government to put upon the manufacture of spirits used as a beverage the heaviest excise compatible with successful collection, a moderate excise on fermented liquors derived from grain and hops, and to encourage the production of light table wines by leaving them free. Moreover, it is desirable to diminish the number of tippling houses, and this is most effectually accomplished by imposing so high a license-tax as to suppress nearly all. Licensed dealers then, instead of combining to resist the law, would unite in its support, in order to prevent encroachment on their dearly bought privilege. In order to discriminate between bar-room and home consumption, it would be advisable to impose a lower license for sale of fermented liquors than that of spirits, and lowest on sales of one gallon and upward of all liquors. This could be effected by separate licenses for fermented liquors, and for liquors in bulk and by the glass for consumption on the spot.

It is undeniable that the liquor traffic is responsible for much of the crime and poverty which afflict society and much of the disease which shortens human life. The question of its control is one of the most serious and difficult problems which confront moralists and legislators. In the opinion of the writer, it should be dealt with by practicable methods, in the spirit of truth. It is untrue that alcohol is, on all occasions, under all circumstances, at all times, in all quantities, a poison, and therefore harmful. It is no more true of alcohol than it is of all the condiments used in our daily food, of tobacco, of most of the medicines that physicians prescribe. They all have their uses, and the harm comes from their abuse. Except as a medicine, alcohol should only be taken largely diluted, along with food or soon after eating, when it aids digestion and forms an addition to ordinary food. Most of our people in their usual health do not need it and are better off without it. Undue plethora is the least harmful of its effects on those who have plenty of wholesome food and stomachs suited thereto. Many who do not need alcoholic beverages, but are content to use them in moderation, readily become tolerant, as they do of tobacco, tea and coffee. Such are many millions of consumers of light wines and beer in Europe, and there is the strongest probability that, if deprived of their customary beverages, they would resort to substitutes more energetic and positively harmful, as is actually the case recently in France. Witness also the increased use of narcotic and anesthetic drugs in this country, under stringent repression of the liquor traffic.

The subject has been clouded by fallacies to such degree that most people fail to distinguish between temperance and total abstinence, moderation and intemperance. The utterances of those engaged in the crusade against alcohol are of the most intemperate character, abounding in loose statements and bad reasoning. The preaching of brimstone and hell-fire is rapidly dying out in our pulpits, because intelligent persons discredit the doctrine and are disgusted by it; and now, in the clear sunset of the nineteenth century, it is an anachronism to invent false alarms, which do not frighten people of average sense.

322 Haight Street.

HUMAN FOOD LAWS.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY ROBERT W. HASTINGS, M.A., M.D.

BROOKLINE, MASS.

"The comfort, energy, usefulness and moral character of a man depend largely upon his digestion, and this in turn depends largely upon what it has to act upon, viz., food." (Wm. Pepper.)

In view of this it is strange how little interest man has taken in the regulation of the quality of that food. First and last, in one place or another, mankind has eaten nearly everything which by mastication could be made small enough to pass down his throat. But the great mass of humanity always has and does still subsist upon a few abundant, nutritious and easily obtainable foods. Such are found in fruits, grains and vegetables. Different peoples and races have made use of quite different kinds of foods. But with the more intimate knowledge of others' tastes, each of the so-called civilized nations has adopted certain of the customs and habits of others, and among them the foods. Thus our dietary has rapidly increased. Not until recent years has there been any careful scientific study of man's needs, and still more recent have been the attempts to really satisfy those needs. There can be no doubt that too much food does fully as much harm in the world as too little, and too much of any one kind far more than either. Good evidence of the advantage derived from a regular ration of food arranged on a scientific basis is seen in the uniform good health of well managed modern armies and large institutions. Careful analyses of physiologists and chemists show just how many grams of proteids, fats, carbohydrates, salts and water are needed to maintain the average human life in its best equilibrium. We are becoming more and more interested in these questions, and are quietly making practical application of the lessons learned in the laboratories of the scientists.

But it may well be questioned whether mankind as a whole, and particularly that portion of it dwelling in these United States, are by any means ready to accept rules as to what and when they shall eat. Like animals or plants they insist on eating and drinking whatever they like or is most convenient.

With regard to the quality, however, there is really appearing considerable interest. No man likes to be cheated. Prove to him that he is being defrauded in the food he buys and he will make some attempt to check the fraud. If you can further prove that he is being injured by that food, another and stronger motive for interest is aroused.

The adulteration of food is of very ancient origin, and has from time to time been sharply checked. But

such action has until recently always been spasmodic. The object of adulteration is to make money. The dilution must, therefore, be made with some material cheaper than the food itself, not readily detected by sight, taste, smell or touch, and if practicable not sufficiently harmful to cause rapid poisoning and consequent detection. The mere fact that the food furnishes insufficient nutrition or is slowly or indirectly harmful, does not at all trouble the rascally manufacturer or dealer.

In the matter of systematically stopping these frauds some European countries have been much in advance of the United States. Thus England, France and Germany had good laws before any serious agitation had begun on this side of the Atlantic. It would be interesting to compare these European methods with the best American methods, but time forbids. As matters of history, however, we may note that England passed extensive food laws in 1860, 1874 and 1879.

France has had quite definite laws for many years, gradually, without any great movement, reaching their present form.

Germany, too, has long had good laws in this matter, which were put in their present form in 1879.

At that time 231,478 analyses were made and only 3508 or 1.5 per cent. were found adulterated. In view of the fact that over 150,000 of these samples were milk, this is remarkable.

About twenty years ago Americans began to seriously think on the matter. A great many books and magazine articles were published and the public interest gradually aroused. Of course the medical profession led in the matter. Investigation showed that very many articles of food were adulterated to some extent. The United States Commissioner estimated this adulteration at nearer 15 than 5 per cent. When we consider that the value of the food consumed was \$4,500,000,000, the enormity of the crime is apparent.

Most of the States have laws prohibiting adulteration in general, but the laws are not enforced and are not comprehensive enough. In 1879 careful study was begun on the subject by a committee consisting of the Vice-President of the National Board of Health and one representative each from New York, New Jersey and Massachusetts. These three States later adopted the recommendations of this committee. Ohio and Connecticut have since passed comprehensive laws in the matter and the results have been most satisfactory.

Since the United States' Special Agent, Alexander J. Wedderburn, says that "Massachusetts has very carefully investigated the question of food adulterations, and has probably the fullest and most complete laws upon the subject in this country," it will be helpful to consider the progress of the movement in that State.

When in 1870 the State board of health was established there were in existence a few special laws in regard to certain adulterations. There was no general law and no specially deputed persons for the enforcement of the special laws.

The first duty was the examination of the supply of fresh beef furnished to the city of Boston. Their report led to the enactment of laws which have served as models to other States. Then they found that 85 per cent. of the milk sold in Boston was adulterated—a great contrast to Germany. Other foods were almost as bad.

As a result of their continued reports to the legislature the general food law was enacted in 1882. A large

number of examinations were made and numerous prosecutions instituted. What was more to the point many convictions were secured. Still in 1886 60 per cent. of the foods examined showed adulteration. Two years later, however, these were reduced to 36 per cent. and there has been steady improvement ever since. The report for 1894 showed 6874 samples examined by the State analysts of which 2190 were not up to the standard, a percentage of 31.91 of adulterations. This does not really show the amount of adulteration but only the per cent. in selected articles. The greater the care taken in the selection, the higher will be the per cent. found. The same improvement could be shown in New York, New Jersey, Ohio and Connecticut. But it will be more profitable perhaps to consider briefly these laws and how they have been and may be applied.

According to the Massachusetts law a food is deemed adulterated: "1, if any substance or substances have been mixed with it so as to reduce or lower or injuriously affect its quality or strength; 2, if any inferior or cheaper substance or substances have been substituted wholly or in part for it; 3, if any valuable constituent has been wholly or in part abstracted from it; 4, if it is an imitation of, or is sold under the name of another article; 5, if it consists wholly or in part of a decomposed, putrid, or rotten animal or vegetable substance, whether manufactured or not, or in the case of milk if it is the product of a diseased animal; 6, if it is colored, coated, polished or powdered whereby damage is concealed, or if it is made to appear better or of greater value than it really is; 7, if it contains any added poisonous ingredient or any ingredient which may render it injurious to the health of a person consuming it."

The members of the State Board of Health were made the agents of the Commonwealth to secure enforcement of this law and were given at first \$3000, then \$5000, next \$10,000 and finally \$11,500 to expend in so doing. Inspectors and analysts were appointed. Vigorous action has characterized the board from the outset. From 1883 to 1895 there were 1131 complaints made in court; and among these 626 were for adulterating milk. One thousand and twenty-eight convictions have been secured and fines amounting to over \$25,000 imposed.

By provision in the statute three-fifths of the appropriation must be expended "for the enforcement of the laws against the adulteration of milk and milk products." It was found that the milk was occasionally colored by annatto, caramel or flour, but that the chief adulteration came by the addition of water or the removal of cream. It is stated on good authority that to the 120,000,000 gallons of milk brought into New York City in 1883 40,000,000 gallons of water were added.

In English cities the percentage of milk samples found to be adulterated is almost the same as in the United States. Thus 1633 out of 12,151 were found to be adulterated. France, however, does much better, there being only 279 frauds detected in 4315 samples. Doubtless this is due in part to the low standard.

This suggests a difficulty which has confronted the authorities from the first, viz., the need of a fair standard. After much study of averages it was fixed in Massachusetts at 13 per cent. of solids. New York and New Jersey require 12 per cent. of solids, of which 3 per cent. must be fats. England and France and

Holland only require 11.5 per cent. of solids, of which 2.5 per cent. must be fat. Ohio's requirement is the same as New York's. Apparently it is a little more fair than the 13 per cent. of Massachusetts. Evidence of this is seen in the fact that in the latter State of 3549 samples examined in 1894, 1597 did not contain 13 but did contain 12 per cent. The enforcement of the law in Ohio is entrusted to the Dairy and Food Commissioner, and last year he was allowed over \$50,000 to expend. As a result he is able to report: "greater attention paid by dealers to the quality of goods sold by them than has ever been done before. Immense amounts of bad goods have been shipped out of the State and manufacturers from all parts of the country are anxious to ascertain the requirements of law previous to sending goods into the State. In many cases manufacturers have informed me that they find it is necessary to put up one class of goods for Ohio and cheaper goods to be sent into States where laws were not enforced." He further declares "more work has been done in the prevention of fraud in the sale of food and drug products, and in the preservation of the public health thereby in the State of Ohio during the past ten years than in all the other States of the Union combined." All honor to Ohio! But shame on the other States!

But there are food laws which are manifestly unfair. Like many portions of our tariff laws they benefit only a few or a class.

About twenty years ago a French scientist named Mège-Mouriéz noticed that cows continued to give milk which contained cream, even though they were cut off from all fat-producing foods. Manifestly some of their reserve supply of fat must be transferred to the milk. He began to experiment with these fats and found that by proper chemie and mechanical means he could produce a compound closely resembling chemically and macroscopically the familiar butter. Physiologists tested it and found that for all practical purposes oleomargarine was as useful a food as butter. As it could be made for about one quarter the cost of butter, the discovery was hailed as a great boon for the poor. Suddenly the farmer awoke to the situation. He was losing the market for his butter. Legislatures were appealed to. A very large proportion of the legislators were farmers themselves. Countless stories, most of them false, were concocted telling of the foul constituents and dreadful methods used in its manufacture. The result is a series of laws which are practically prohibitory and the loss to mankind of a valuable food. As physicians we should do our utmost to promote a reasonable regulation of the manufacture of such foods; for we know how sadly they are missed in the dietary of the poor.

Another article of food which was found to be frequently adulterated was cheese. The milk fats were left out by skimming the milk, and other fats, lard most commonly, worked in. In the detection of these frauds the microscope has been very valuable. Numerous laws for the protection of the public have been passed in the different States, which in some respects resemble the oleomargarine laws. The fight has not been as bitter, however, nor the laws as unfair. Thus in New York, Wisconsin and Minnesota, makers of "full cream cheese" are allowed to use an official stamp. To use this stamp on any cheese not "full cream" is to render one self liable to severe penalties. Ohio and Colorado go a step further and require the "skimmed" and "imitation" or "filled" cheeses to be so stamped

with an official stamp several inches square. The other States have not troubled themselves very much in this matter.

Flour is only rarely adulterated, for as we noted at the outset, adulteration is practiced only to make money. Sugar is another great staple food which is now only rarely adulterated. Owing to the ease with which the taste and color could be imitated, vinegar has been much manufactured. Some States, Massachusetts for instance, have therefore established by law the percentage of apple substance which vinegar must contain as well as the per cent. of acetic acid, viz., $4\frac{1}{2}$ per cent. Honey and maple syrup are two common articles of food which need constant inspection; and there are a multitude of others. Let me quote a few of those frauds detected by the Ohio inspectors in 1896 and punished by Ohio's laws; candy containing the poison anilin black; tomato catsup containing salicylic acid; canned peas colored by oxid of copper, oxid of lead and oxid of tin; black pepper containing buckwheat, roasted cocoanut shells and cayenne pepper; molasses adulterated with commercial glucose; buckwheat flour adulterated with wheat flour; cloves deprived of oil; green peas colored with the salts of copper; cider containing salicylic acid; raspberry jelly made of ether, alcohol and anilin red; current jelly composed of glucose syrup and salicylic acid; coffee adulterated with chicory, peas, corn and wheat bran. Truly the American is ingenious!

These facts are not secrets. Why, then, are there not more States with comprehensive laws? Why do not the States with good laws allow sufficient money to its agents to enable them to do good work?

More than seven billions of our money are invested annually in our food and drug product. Millions on millions of this finds its way to the dealer in adulterated products. And in these days it is the money power which secures legislation. Not always, however, and not necessarily. As physicians with a wide influence, let us agitate the matter, stir up and instruct public opinion, and it may not be many years before great results shall be attained both for the health and wealth of our people.

DIET IN THE CHRONIC CATARRHS OF THE GASTRO-INTESTINAL TRACT.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY BOARDMAN REED, M.D.

PHILADELPHIA, PA.

In treating of diet in the chronic catarrhal inflammations of the stomach and intestines it is not intended to limit the discussion to those cases only which are usually classed as such. Our present exact methods show that chronic gastric catarrh in its earlier stages is rarely accompanied by nausea or vomiting and not always by pain in the stomach itself; also that cases of gastritis grave enough to have seriously impaired the health may be characterized by an increase rather than by a diminution of the appetite.

Again the same methods prove the frequent coex-

istence of catarrhal disease in the small intestines and persistent constipation or constipation alternating with diarrhea when the disease has become more advanced. Obstinate chronic diarrhea points usually to an aggravated catarrhal inflammation of the intestinal mucous membrane complicated in many cases with ulceration.

A proper regulation of the diet is important in most derangements of health—perhaps in all. In those involving the digestive system it is peculiarly important. The science of dietetics presupposes that the appetite is not a safe guide in all cases and experience abundantly confirms this view. In the matter of quantity alone there are numerous patients who habitually eat too much and many more who, in consequence usually of a faulty secretion of the digestive glands, eat too little. It can not be too strongly emphasized, however, that patients suffering with chronic catarrhal inflammation of the digestive tube require a strongly nourishing diet. Their nutrition is apt to be low and commonly shows a strong tendency to sink lower. A portion of their food fails of its intended purpose by undergoing fermentation or putrefaction instead of digestion and assimilation. In this way there occurs not only a positive loss to the organism of much needed pabulum, but a still greater injury through the absorption of toxic substances resulting from these morbid processes.

To offset the depressing effects of this two-fold injury there is often a craving for food in abnormally large quantities, which when taken in the three usual meals daily, embarrass the system and aggravate the existing disease by overburdening the viscera, producing stagnation and retarding digestion with dilatation as an ultimate consequence. One remedy in such cases is to prescribe more highly concentrated and nourishing kinds of aliment in the most easily digestible forms possible, and when this does not suffice to fulfil the needs of nutrition without overtaxing the organs, then to prescribe smaller meals and more of them.

Numerous theories are current as to the particular forms of diet best adapted to these catarrhal affections and much diversity of practice has resulted. A reliance chiefly upon the cereals, vegetables and fruits has been urged, especially in France, by Dujardin-Beaumetz and others, and still has earnest and honest champions in some of our American sanitariums. This vegetarian system, in addition to its cheapness, has a number of manifest advantages in its comparative asepsis, its laxative tendency, its palatability for most patients and its valuable nutritive qualities, maintaining the strength well and when it agrees often putting on flesh rapidly. Yet the observations of many physicians and my own experience in its use indicate that it is not a safe diet in the diseases now under consideration, except possibly in the mildest forms of intestinal catarrh associated with constipation. These foods disagree because they are highly fermentable and often irritating to the chronically inflamed mucous membranes.

A nearly exclusive milk diet has its votaries and in certain cases proves curative, especially when the milk can be obtained pure and comparatively fresh from the cow. The ordinary commercial milk of cities is always from one to three days old when served to the customer, and is often handled in such a careless manner as to become dirty and infected with all manner of germs, even when it escapes the grosser impurities

resulting from its admixture with contaminated water and adulteration of drugs to counteract the effects of too long keeping. Happily, however, this difficulty has recently been well overcome in many of the larger cities and it is now possible, for the well-to-do classes at least, to obtain, in sealed jars, milk which when furnished by honest dealers, is comparatively pure and aseptic, and usually not more than twelve to twenty-four hours old.¹ Such a milk properly modified or diluted may be given very largely in many catarrhal cases with the utmost advantage, especially when a little good bread or toast or sometimes a few eggs are added to the daily allowance. But this method employed in a merely routine or empirical way without any exact knowledge as to either the motor power of the stomach or the faults in its secretory function is capable of doing harm. When there is much gastric dilatation or even marked atony, milk or any liquid taken in large quantities is liable to aggravate; and when the stomach is badly infected the same food is apt to ferment rapidly. It suits particularly well as a rule, in those forms of chronic diarrhea where the pancreatic secretion has been well preserved. However, as Ewald so well says: "It must also not be forgotten that an exclusive milk diet is a kind of slow starvation, and that to live on milk alone would require much larger quantities than the capacity of the stomach would allow."² Hence such a diet can not be long persevered in without unduly lowering the strength.

In chronic gastric catarrh Ewald and most of the German authorities advise a mixed diet without any very severe restrictions. They allow meats, eggs, milk and many of the carbohydrates, proscribing, however, freshly baked breads, etc., as well as the coarser vegetables, strong acids, sharp condiments and the stronger liquors. They recommend that the starches shall have been changed so far as possible into dextrin before their ingestion and object to dishes cooked with much fat. Ewald particularly objects also to fat meats and the oilier kinds of fish, hard boiled eggs and the tendinous parts of meat. Boas³ takes very similar ground, but like various other German writers, prescribes diet tables with definitely weighed proportions of the proteids, fats and carbohydrates for each meal. Both Ewald and Boas very properly caution against too sweeping and arbitrary prohibitions of whole classes of foods in the diet of dyspeptics generally, since every patient has idiosyncrasies which need to be studied individually.

The American method of limiting these patients for a time mainly to lean meat and hot water, though on a *priori* grounds irrational and unsafe, has borne well the crucial test of experience in a large number of cases in the hands of several able physicians. In the bad cases the patients are put at once on the pulp of broiled lean beef or beef which having been finely chopped and deprived of all the fat and tendinous parts is afterward broiled in small cakes. With these is given usually a very small portion of stale bread or toast without butter and a very little raw celery or lettuce—sometimes also asparagus tips or stewed celery with occasionally one orange or baked apple

¹ Dr. Samuel G. Dixon, president of the Academy of Natural Sciences, Philadelphia, has called my attention to the fact that sometimes the men who deliver these jars refill them without cleansing, which would be highly dangerous when they have stood for hours in infected sick rooms. B. R.

daily or a few white grapes, the skins and seeds being rejected. Coffee and tea may or not be allowed, but the patient is required by most advocates of the method to drink from one to two quarts, and sometimes three quarts, of hot water every day. As improvement sets in and fermentation lessens, the number of articles permitted is gradually enlarged, but upon the first sign of a relapse the strict meat diet is resumed.

In other cases where the digestion is somewhat better, lean meats are allowed from the start in the usual forms of tender beefsteak and lamb chops, the fat and gristle being rejected.

Carried out with extreme rigorousness in cases adapted to it, this system of diet will in the course of four or six weeks, even without the aid of stomach washing, often greatly lessen fermentation. It will ameliorate markedly many stubborn cases of gastric or intestinal catarrh and according to the testimony of some of its most zealous champions, may even, when followed up later in a modified form, effect a radical cure, though not usually before the end of two or three years.

The more enthusiastic advocates of this exclusive diet recommend it as a rule in all cases of gastro-intestinal catarrh, and it can not be denied that in a considerable proportion of such cases when intelligently directed and faithfully carried out, it does well. It supplies an abundance of highly nourishing albuminoid material in a form which is comparatively easy of digestion, and at the same time is very much less fermentable than most other foods. It is also of small bulk, except when inordinately large quantities of water are taken, thus aiding in overcoming dilatation of the stomach and bowels. The chief objection to it is that the proportion of carbohydrates and fats is far too low to support nutrition well for any great length of time. Then, too, the large quantities of hot water often required to be taken with the meat in order to keep up a sufficiently active elimination, have important contraindications. When the heart is very weak, a serious embarrassment may result from throwing into the circulation such unusual amounts of fluid, and when there is much dilatation or even marked atony of the stomach walls, these conditions are almost sure to be aggravated by taking in so much fluid.

Another objection to the routine employment of such an almost exclusive meat diet is that it is excessively stimulating to the gastric glands in cases where hyperchlorhydria complicates chronic gastric catarrh.

Until recently the possibility of the coexistence of these two conditions was not recognized, but various observers have shown of late that we may have an acid gastritis that is a true catarrhal inflammation, along with a highly excessive secretion of hydrochloric acid. My own clinical work has confirmed this view. Experiments conducted in my laboratory have demonstrated, as mentioned in a previous paper,¹ that a meat diet powerfully excites the secretion of hydrochloric acid, thus tending to exaggerate the condition of hyperchlorhydria.

Numerous patients were put on a diet of meat mainly and the stomach contents analyzed every one to two weeks after the usual Ewald test breakfast. Some of these patients had in the beginning a normal

proportion and others an excess of hydrochloric acid. The result was almost without exception a decided increase of the acid while on the diet. This was especially true in all the cases of the hyperchlorhydries, except where the stimulating effect of the diet was counteracted by large doses of an alkali and sometimes even in spite of this. Evidently, therefore, this diet however useful in suitable cases, would be unsafe as a routine method in all, without thorough analysis and tests in every case.

Personally, I have found more difficulty in getting patients to carry out the meat-and-hot-water method, with the necessary strictness, for many months together, than in inducing them to submit to lavage with a diet somewhat more liberal though on similar lines. My results, too, in chronic gastric catarrh have been better since I have been employing lavage along with a diet in which lean meat, eggs and milk predominate, excluding sugar, shellfish, hot or fresh breads, fried foods, all the less digestible vegetables as well as the coarse cereals and restricting starch foods to a few of the blandest in small amount. Stimulants and the stronger condiments are cut off as a rule, to which there are some exceptions. All the more acid fruits, especially those with small seeds, and all hard and gritty articles incapable of perfect solution, are strictly forbidden. In the worst cases I frequently, at first, prescribe either the pulp of lean beef or juice expressed from the same as almost the only food for a few days. When perfectly fresh eggs can be had they are usually added, being eaten either raw, soft boiled or poached. The whites beaten up and taken raw agree well even when the stomach is very irritable and make an ideal food. Then gradually the dietary is enlarged, watching the effects upon the urine, mucous secretion, body weight and condition generally.

In the pronounced cases of gastric catarrh with an excess of hydrochloric acid (acid gastritis) I often find it necessary to restrict the dark meats especially, ordering eggs and milk instead, with the gluten preparations and a small amount of white wheaten bread, preferably in the dryer forms so as to obtain a larger admixture of the saliva. The farinaceous food in these cases should be predigested so far as possible by heat. It is sometimes well to let the patient take daily one lunch or light meal consisting mainly of bread or other preparations from grains, changed so far as it is practicable by heat into dextrin, as in the form of toast or zwieback or the various malted foods. Good fresh milk is a good accompaniment of such a meal. Otherwise he should be advised to take whatever carbohydrates there may be allowed, in the early part of one or more meals, following these later with meat or eggs. In this way the salivary digestion is given an opportunity of proceeding well on toward its completion before the time—usually about twenty to thirty minutes from the beginning of the meal—when the secretion of hydrochloric acid has become large enough to arrest the process.

In the cases of gastric atrophy in which there is practically no longer any secretion in the stomach, I have not found a meat diet to suit well as a rule, even when full doses of hydrochloric acid and pepsin are given. Sometimes eggs raw or lightly boiled agree better. Here, however, the best grades of the cereal preparations made of finely ground and bolted flours or meals with milk peptonized or not, according to the condition of the pancreatic and intestinal secre-

¹ "The Excessive Secretion of Hydrochloric Acid by the Stomach and its possible serious Consequences." By Boardman Reed, M.D., International Clinics, vol. i, seventh series, 1897.

tions and with the addition usually of a certain amount of eggs, has seemed to succeed best.

But in the cases of chronic gastric catarrh in which the secretion of the hydrochloric acid is merely diminished, the results from a diet of meat and eggs chiefly are often excellent. To supplement the work of the stomach glands hydrochloric acid can then be administered in quite small doses with usually the happiest results.

Observations in my laboratory have shown beyond question that 0.3 to 0.6 c.c. of the dilute hydrochloric acid given during the period of digestion in such cases tend strongly to promote the secretion of the gastric glands, so that it is not uncommon to find after a few weeks of such treatment, even when not conjoined with other roborant measures, a largely increased percentage of the acid as shown by analysis after the usual test meal.

In intestinal catarrh the selection of the diet must turn largely upon the condition of the stomach digestion. When the case is complicated by hyperchlorhydria the diet above recommended for that condition will generally be the most suitable. These are cases in which a milk diet frequently gives the best result. The same with the cautious addition of meat juice and eggs will usually agree well in cases of intestinal catarrh with very small or absent digestive power in the gastric glands, provided any deficiency in the secretion of the pancreatic juice shall be made up by the administration of a good active extract of pancreas.

When the intestinal catarrh is conjoined with good stomach digestion—a not very frequent combination however—there may be a full allowance of meat along with the blandest vegetables and farinaceous foods, though even here milk and eggs will often agree better.

PHYSIOLOGY OF THE COLON, SIGMOID AND RECTUM.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. G. CARPENTER, M.D.

STANFORD, KY.

In obscure cases of disease of the rectum and sigmoid flexure, inversion of the trunk seventy to eighty degrees, dilatation of the anus with Sims' speculum, intiation of the bowels and electric or reflected light (the former is preferable), are indispensable to a thorough ocular examination and diagnosis. In such cases I have used a rubber tube, eighteen inches long, with good results. By inversion of the trunk seventy or eighty degrees the pelvic and abdominal contents gravitate toward the diaphragm; a vacuum is formed in the rectum and sigmoid which become inflated with air under forced expiration and anus patulous and retracted with a Sims' speculum; the mucous folds are effaced, and the bowel has almost the appearance of a straight tube; on inspiration the bowel collapses and presents a curved tube, the mucous folds resuming their normal position.

The upper end of the rectum is much smaller than any other part of it, and presents a cavity closed from the sigmoid flexure, because the circular muscular

fibers of the latter act as a sphincter, except during forced expiration and defecation; at such time the rectal cavity and lower part of the cavity of the sigmoid flexure seem one. Gray's "Anatomy," page 806, states that the sigmoid flexure is the narrowest part of the colon.

The rectum is cylindric, not sacculated like the rest of the large intestine. It is narrower at its upper part than the sigmoid flexure, gradually increasing in size as it descends and immediately above the anus presents considerable dilatation. It is capable of acquiring enormous size; when distended it is funnel-shaped and naturally is a closed cavity caused by approximation of Houston's folds and action of the circular muscular fibers. "The sigmoid flexure has great mobility, with the hand introduced into the bowel a point above the umbilicus has been reached."

Ocular examination of the cavities of the rectum and sigmoid flexures, though one is expert in handling instruments and focusing reflecting light on the parts to be seen, is no easy feat to accomplish except by practice. The subject to be examined should be slender and emaciated and willing to bear some slight pain and discomfort in the accomplishment of inspection; the sphincter ani should be previously dilated or relaxed and dilatable. If sunlight is reflected into the rectum the head of the patient should be toward the sun, if other light be employed it should be to one side—the left is preferable. The trunk must be inclined to the left side and inverted to an angle of seventy or eighty degrees and the thighs flexed; both should be supported on hard pillows. The speculum (Sims') is introduced into the anus and rectum, retracting the former, the lower and about half of the middle third of the latter with the coccyx. The nates must also be retracted. The anterior rectal wall, or recto-vesical wall, and anterior wall of sigmoid flexure are to be pressed forward out of the way by the blunt-pointed sound or applicator, or by inflation of air, the retraction of the anus and rectum pressing the anterior rectal wall and the anterior wall of the sigmoid flexure forward. The reflection of light or use of the electric lamp introduced within the bowel must be done simultaneously with forced and prolonged expiration.

The function of the sigmoid flexure is a receptacle for the feces as they pass from the descending colon, it being closed at its lower end by circular muscular fibers separating the sigmoid flexure from the rectum. The shape of the sigmoid flexure lessens or breaks the force of gravity of the feces; if the bowel at this point was a straight tube the intestinal contents would descend at once to the anus and cause continual inclination to defecate in the sitting or erect position. When the sigmoid flexure becomes filled normal reflex action by the spinal nerves is produced, causing contraction of the circular and retraction of the longitudinal muscular fibers, by which the length and lumen of the bowel are made less above; the circular muscular fibers of the lower end of the sigmoid flexure and those of the rectum, the sphincters ani included, relax and with the volition of the patient defecation is accomplished, the lungs being inflated, and the diaphragm and abdominal muscles contracted, thus lengthening the contents of the abdominal cavity.

Another function of the sigmoid and rectum and colon is to absorb nutritive enemata and sustain life in gastro-intestinal diseases. Physiologically the rectum is a closed and empty cavity (except during forced expi-

¹ At Winchester, Ky., June, 1886, the author read a paper before the Kentucky State Medical Society on ulceration of the sigmoid cavity. "Inversion of Trunk, Electric and Reflected Light in Diagnosis and Treatment," which was published in the American Practitioner and News, Vol. 2, New Series, No. 17, August 21, 1886, at Louisville, Ky. On Nov. 30, 1886, the writer was the first to do sigmoidoscopy.

ration and defecation), and separated from the sigmoid cavity above by contraction of the circular muscular fibers of the latter at its lower end. The rectum has the following mucous folds, viz., the longitudinal fold at the lower part of the bowel and Houston's folds, each being half an inch wide and semilunar in shape, these are sometimes three or four, but sometimes only two. One is situated on the right side of the rectum near its upper end, one on the left side lower down; the largest one on the anterior rectal wall opposite the bladder and the posterior fold on the rear wall of the rectum an inch from the anus. These folds with the circular muscular fibers of the rectum and of which the sphincter ani is composed, together with the levator ani and coccygeus muscles, act as a support to the sigmoid flexure when it is filled with fecal matter. When defecation is postponed, though the desire is present and urgent and feces have passed into the rectum, the latter by contraction of its circular and longitudinal muscular fibers (the mucous folds acting as valves or elevators) returns the feces to the sigmoid cavity. After the desire to defecate has passed the rectum is found to be empty. But, should defecation be habitually postponed from day to day or two or three times a week, though demand is urgent, the bowel becomes habitually distended, fails to contract or retract, and the rectum instead of being physiologically empty, becomes pathologically distended and relaxed. Constipation or diarrhea would then cause the same relaxation of the involuntary muscular fibers.

The glands or crypts of Lieberkühn are simple tubular depressions of the intestinal mucous membrane, thickly distributed over the whole surface both of the large and small intestine. In the small intestines they are visible only with the aid of a lens, and their orifices appear as minute dots scattered between the villi. They are larger in the large intestine and increase in size the nearer they approach the anal end of the intestinal tube; in the rectum their orifices may be visible to the naked eye. In length they vary from $1/180$ to $1/160$ of an inch. Each tubule is essentially similar in construction to the intestinal mucous membrane, viz., a fine basement membrane, a layer of columnar epithelium, many of which cells are goblet cells lining it and capillary blood vessels covering its exterior, the free surface of the columnar cells presenting a striated appearance.

The mucous membrane of the large, like that of the small, intestine is lined throughout by columnar epithelium, but unlike it is quite destitute of villi, and is not projected in the form of valvulae conniventes. Its general microscopic structure resembles that of the small intestine, and it is bounded below by the muscularis mucosae. The general arrangement of ganglia and nerve fibers in the large intestine resembles that in the small.

Glands.—The glands with which the large intestine is provided are of two kinds, the tubular and the lymphoid. The tubular glands, or glands of Lieberkühn, resemble those of the small intestine, but are somewhat larger and more numerous. They are also more uniformly distributed. They increase in size the nearer they approach the anal end of the intestinal tube. In the rectum their orifices may be visible to the naked eye.

Nutritive liquid material in the rectum, sigmoid and colon enters the circulation through osmosis and filtration. Crystalloid substances as alcohol, sugar,

ordinary saline substances should be combined with the liquid nourishment to hasten absorption.

The diffusibility of the substance to be absorbed is one of the chief conditions. It should be a liquid or gaseous one, as the less dense the fluid the more speedy, as a general rule, is its absorption by the lymphatics and blood vessels. The more anemic the patient and the less congested the blood and lymphatic vessels the more rapid is the absorption process. The more tense the vessels the less rapid is absorption; absorption may be entirely suspended from arrested function, by congestion and inflammation of rectum, sigmoid and colon with full and tense vessels, therefore a healthy rectum, sigmoid and colon are highly essential to feeding by this route. The more rapid the circulation, without inflammation, in rectum, sigmoid and colon the quicker is absorption accomplished. A colitis, sigmoiditis or proctitis with or without anal fissures, ulcer in lower third of rectum, acute or sub-acute inflammation of hemorrhoids or malignant disease will interfere seriously with feeding per anum. At least once a day the colon should be washed out with a warm antiseptic solution of from one to four pints: the patient in Carpenter's posture, viz., on left side, left shoulder and side of head with hips raised to an angle of 40 to 80 degrees. Through gravitation and retrograde action of the longitudinal and circular muscular fibers of the rectum, sigmoid and colon the enema will reach the caput coli. Weak crystalloid solutions are more readily absorbed than strong ones. The chlorid and the carbonate of lithium are most easily absorbed by an empty stomach and doubtless the same is true of an empty colon. The epithelium as well as the glands and blood vessels is a prominent factor in colonic absorption and alimentation. Strychnin in solution and some other drugs are more quickly absorbed by the rectum than by the stomach.

Dr. J. Peyton of Stanford, states that he nourished a lady for three weeks by rectal alimentation with peptonized beef, white of egg and sweet milk given every four to six hours. Patient had gastro-enteritis; recovery followed.

A physician of Louisville nourished for more than a year a patient who had ulceration of the stomach, with sweet milk and whisky only, per rectum.

Another physician nourished a patient three weeks with enemata of bovine. Patient was weighed before and after this method of feeding and had not lost any flesh.

Mrs. —, age about 43 years, had mental aberration and would not eat or swallow her food. Family would not consent to feeding by stomach tube, hence rectal alimentation was used. Four to eight ounces of warm milk and a tablespoonful of whisky were given every four to six hours, with hips elevated high during and for half an hour after the use of the nutrient enema. Rectal treatment continued three weeks. Recovery of patient complete.

Mrs. A. T., age 44 years, had mental aberration: would not eat or swallow. She was nourished for six weeks with enemata of sweet milk, whisky, quinin and sodium chlorid administered high up in the rectum by elevating the hip from 40 to 60 degrees. With elevation of the hip on the left side the pelvic contents gravitate to the diaphragm, the rectum and sigmoid retrograde and the nutrient enemata are forced into the descending and transverse colon. Inunctions and massage with olive oil every four hours were also used. At the end of six weeks the patient was stronger

and had gained some flesh. Unfortunately she was not weighed before and after the course of treatment. The patient recovered.

Miss —, age 28 years, had typhoid fever. Deafness, amblyopia and semi-unconsciousness occurred in the third week of the disease, with inability to swallow. There were no signs of hemorrhage of the bowels at any time; pulse was exceedingly feeble and dicrotic, often imperceptible. Hot or warm milk, c.c. 118 to 237; sodium chlorid, grams 2, and whisky, c.c. 30 were given, per rectum, every four to eight hours night and day for three months or more. At times the whites of one or two eggs were added to the milk, or a warm egg-nogg was given per rectum.

L. T., age 2 years, a negro child, first had scarlet fever, then diphtheria. In three weeks from date of contracting diphtheria the palatal and pharyngeal muscles were in a state of paresis, and patient could not swallow. Rectal feeding was resorted to with satisfactory results. Milk, c.c. 118; whisky, c.c. 7.4; quinin, grams 13, and salt, gram .65 were mixed and injected warm into the bowel every four to eight hours. Rectal feeding was continued over a period of two months.

The writer has repeatedly passed enema to caput coli by elevating the hips.

A patient now at the Joseph Price Hospital, Stanford, Ky., who had chronic gastro-enteritis for years had a subacute attack and for three weeks or more has been fed with nourishing and stimulating enemata and is improving nicely.

The last four cases, in addition to the stimulating and nutritive enemata, were given the tincture of nuxvomica.

Aphorisms.—The rectum, sigmoid and colon must be washed out once or twice a day with hot sterilized water to which has been added carbolic or boric acid.

Hot or warm soothing, non-irritant, nourishing, stimulating or sedative and tonic aseptic enemata can be used in rectum with impunity. Whisky, brandy, alcohol, salt, sugar or sodium carbonate are crystalloids and hasten absorption. By bringing to the boiling point, then adding pancreatin, sodium carbonate or sodium chlorid prepares milk for colonic and sigmoid absorption. Elevate the hips of the patient to 40 or 60 degrees, secure the advantage of gravity and the retrograde action of the rectum and sigmoid from anus to caput coli. When the hips are thus elevated the anus and lower rectum lose their irritability and reflex excitability, the anus and lower rectum if in a physiologic condition are made patulous and, with the coccyx, are easily retracted. The so-called "passing the rectal tube beyond the sigmoid into colon," as is taught by our college professors can not be done. The author has repeatedly proven that unless you place the patient in the "Carpenter posture" the tube is bent upon itself, one or several times, or the tip descends back toward the anus and the enema is found in the rectum. The safest, surest and best way to intubate the sigmoid is in the Carpenter posture, and best by Carpenter's sigmoidoscopy. Where there are hemorrhoids, anal fissures or ulcers in lower rectum, anal divulsion should be done as a palliative prophylactic measure, under anesthesia.

Rectal divulsions of the sphincters, besides its parietic and therapeutic effects on the lower end of the rectum and anus, causing rest, making the anus patulous and allaying irritability and curing pathologic lesions, has another function, that of nerve-stretching of the fourth

sacral and inferior hemorrhoidal nerves, thereby cutting off connection between the spinal cord, the levator and sphincters, and placing at rest the bladder, rectum, vagina and perineum.

In the Carpenter posture the colon advances toward diaphragm, the sigmoid becomes elongated, loses some of its curves and becomes more like a straight tube—the longer the mesosigmoid the more elongated and less curved the sigmoid, and *vice versa*.

In rectal feeding the enema should always be as warm as can be borne. Beef peptonoids combined with warm milk, bovine and water, with or without whisky or brandy, or hot milk with salt or sugar make nutritive enemata that can be alternated as required. If a tonic is needed, quinin, strychnia or tincture of nuxvomica can be added to the nourishing enemata; if an anodyne, morphin, papin or laudanum can be given in the same manner.

IMPORTANCE OF PHYSIOLOGICAL KNOWLEDGE TO THE GEN- ERAL PRACTITIONER.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY ALBERT E. MILLER, M.D.

BOSTON, MASS.

The lowest form of life is a cell, which is defined as a minute mass of protoplasm. Each individual cell is of sufficient importance to have a life history of its own. It has its origin from some pre-existing parent cell, grows, fulfils its mission, produces other cells, wastes away and dies. All action is attended with waste. There must be food supplied in proportion to this waste or existence would cease. If the supply is less than the waste existence may be prolonged but must finally terminate. If the food supply equals the waste, there will be no apparent change. If it exceed the waste, there will be increase in growth. To keep an animal in a perfect condition the quality and quantity of food should be such as will best supply the place of that which is worn out. In the development of the infant after birth nature furnishes food which is typically perfect. In milk we find all of the various elements necessary for sustaining life and all that is necessary for the nourishing and building up of the tissues. In it we find albuminous material in the form of casein and serum or lac albumin, fats in the cream, carbohydrates in the form of lactose or milk sugar, salts in the form of calcium phosphate. All that is necessary for the development of every part of the system, bone, muscle, nerve, etc., in the right proportions. If from any cause we are obliged to substitute cow's milk, which is too rich in casein and fat, and deficient in sugar, we dilute with water and add sugar so as to bring it more nearly to the composition of human milk. Other foods may be successfully substituted if we keep in mind the exact composition of the typical food which nature furnishes. We should always imitate nature's food as nearly as possible unless from some diseased or deranged condition it is desirable to make a change to meet some morbid demand.

In its mother's milk the infant finds all that it needs for the growth of its body. The casein is used in the development of its muscles and gelatinous tissues. The cream is changed and deposited in the adipose cells or consumed at once to produce the animal heat.

The phosphate of lime is used to develop the osseous system which is now increasing rapidly. If there is a change or necessity to meet, nature modifies the food accordingly. In the case of the calf, colt and animals which commence locomotion very soon after birth, where exercise is often very great, the nitrogenous principle of the milk is increased. This excess of casein is necessary on account of the excessive waste resulting from the extra exercise. Judging from these facts we would naturally, as the child grows older and exercises more, change the food, increasing the nitrogenous principle in proportion, to meet the resultant waste. A knowledge of physiology will enable us to select that kind of food which is demanded by the age, condition and temperature. Foods are usually divided into organic and inorganic. A very convenient subdivision is to divide the organic into first, nitrogenous; this embraces substances consisting of proteid, examples of which are albumin, casein, myosin, gluten, fibrin, legumen, etc.; second, non-nitrogenous, these are: *a*, amyloid or saccharin bodies, sometimes called carbohydrates; examples of these are starches and sugars; *b*, oils and fats, substances which contain carbon, hydrogen and oxygen, the oxygen being less than in the amyloids and saccharin bodies.

Inorganic: first, foods which furnish to the system the required salts; second, liquid food, this is chiefly water. After we thoroughly understand the best diet for perfect health, it is comparatively easy to select a diet for different temperatures and conditions. In very cold seasons and climates we require more heat-producing material. This is furnished by the carbohydrates and the oils and fats. In warm seasons of the year, or if our employment is in a warm room we should diminish the use of these articles in proportion to the change. If our employment requires great muscular exertion we should increase the tissue-making material; the proteids, foods which contain a large amount of nitrogen, such as albumin, casein, fibrin, gluten, legumen. These are to be found in eggs, beef, milk, bread, beans, etc. In diseased conditions we should select the food with still greater care. If, as in fevers and inflammations, there is an excess of heat we should diminish the amount or abstain from the use of heat-producing foods, such as starches, sugars, fats and oils. If there is a lack of exercise and a consequent lack of waste of tissue, we should lessen the tissue-making material. If there is an excessive waste of nerve tissue we should give our patients the kind of food that will compensate for this excessive waste. Experience has taught me that in the treatment of phthisis, neurasthenia and in fact all wasting diseases more may be done with food than with medicine. Medicine may be an aid but the great reliance should be placed upon the food. If in health we are made directly of the food we eat and our condition is influenced by that food, how much more important is this knowledge when our patient is wasting away from disease. Since putting these principles into practice I have not lost a case of typhoid fever and my success in the treatment of other diseases (most notably chronic) has been much increased.

The Initial Manifestations of Leprosy. Prof. O. Peterson concludes from a study of 1200 cases of leprosy, that the mucous membrane is first affected by the bacillus, especially the nasal mucosa. The first manifestation on the skin is in the form of spots, usually red, sometimes symmetric, either on the face or extremities. The nodules develop later.—*Wratsch*, No. 43.

THE REGULAR PROFESSION OF MEDICINE.

Read before the Kalamazoo Academy of Medicine at its Annual Meeting, Jan. 4, 1898.

BY W. H. HAUGHEY, M.D.

BATTLE CREEK, MICH.

The average medical writer is so deeply interested in scientific investigation as to rarely, if ever, think of writing on the subject of the regular profession of medicine. This probably accounts for the scarcity of articles seen on that important subject, but never was the scriptural injunction, "physician, heal thyself," more applicable than at the present time.

The term "regular" is but little understood by the laity, most thinking that any one who assumes to be a doctor, and who obtains his living by the practice of medicine, is a regular doctor because he is nothing else, and while I would fain think otherwise, still I am forced to believe that there are some bearing that proud title that are not clear enough in their understanding of the definition of the word to be ready at all times and at all places, to give a full and clear explanation of its meaning.

I am frequently asked, "Doctor, are you an allopath or a homeopath?" My reply invariably is, "I am neither: I am a regular." That detestable sand-bur, allopath, that was thrown at the regular profession by Hahnemann and still continues to attach itself to our clothing, has done more to befuddle the minds of the laity than anything else, except the apathy displayed by the profession itself regarding it. If every member of the regular profession would immediately and positively repudiate the word as soon as, and on every occasion when it is, applied to us, the laity would soon discard it and we would hear it no more.

The members of the regular profession can no more justly be termed allopaths than they can be homeopaths. Accepting either implies that we rule out some things from our armamentarium, and thereby lessen our usefulness just that much. As the homeopathist uses "similars" to the exclusion of all other drugs, and the allopathist uses "dissimilars" to the exclusion of all others, it is plain that each by curtailing his source of supplies and depending upon those belonging to the creed of his adoption, has lessened his usefulness in exact measure to the therapeutic value of the remedies discarded.

The word "pathy" signifies narrowness, and if a sick man trusts himself to the care of one who follows a pathy, he must simply conform his sickness to the path or pathy. In other words, the practitioner, confident in the infallibility of his pathy, requires nature to conform herself to it, and if she does not, then the patient must die. Fortunately a large per cent. of sick people get well anyway, and nature unaided would effect about 90 per cent. of cures of some kind.

The regular profession rises superior to pathies, and uses anything under heaven that will relieve suffering humanity no matter from whom or what source it comes. Neither must you use large doses, for there is nothing to prevent a "regular" from using infinitesimal doses if he believes it best for his patient.

The regular profession rationally pursued requires a thorough knowledge of physiology, pathology and therapeutics. Then, given a pathologic condition, simply apply the rational therapeutic remedies to quickest and best aid nature to restore a physiologic condition.

There is but one science of medicine, and as science is broad as the universe, it follows that the science of

medicine must be equally broad and embrace every agent under heaven, known or unknown, and is therefore forever at variance with a path or pathy. To the scientific mind there is something so supremely ridiculous in endeavoring to apply a pathy to science or science to a pathy, that were it not for the credence given those who proclaim themselves pathists, the subject would be considered too absurd for notice, but as these pathists are constantly advertising themselves as such, and then covertly using "regular" principles so far as they know, they are therefore practicing the most contemptible deceit on the laity and working a great injustice to the "regular" profession, for by using its principles to obtain results in their work, and then applying the credit of these results to their pathies, the "regular" profession is robbed of the credit due it, which being applied to the pathy makes a double injustice.

To illustrate: Some of the pathists depend so entirely on symptoms as to expose themselves to the charge of being symptomatologists. Now, what does that mean? It means that the remedy is to be decided by the symptoms present, therefore the symptoms must be developed before the remedy can be determined. In fact symptomatology pure and simple, teaches that it makes no difference what you name the disease if you closely watch the symptoms: for certain conditions will cause certain symptoms, so watch the symptoms, treat them and never mind the disease, thus placing entire reliance on symptoms.

Now, note the difference. The regular science of medicine teaches the all-important subject of pathology, built on a thorough ground-work of anatomy and physiology. Pathology, teaching as it does the nature of disease, enables us by our knowledge of it to know in a given disease what symptoms to expect from day to day. To illustrate more plainly:

Patient No. 1 treated by a "regular." Patient No. 2 treated by a symptomatologist.

The "regular" sees his patient and the first thing he does is to make the diagnosis, which he decides to be lobar pneumonia of one day's standing. Knowing the pathologic history of pneumonia he expects a crisis about the fourth or fifth day, and he immediately prepares as best he can for it by applying the known principles of therapeutics applicable to the case, and hopes with good reason to guide his patient safely past the danger point to a good recovery.

The symptomatologist sees his patient and notes fever, quick pulse, rapid respiration, pain in chest or stomach, cough. For each he leaves an appropriate remedy. Next day symptoms, fever, rapid pulse and respiration, more pain, nervousness, cough, which requires a slight change in remedies left. Third day, more pain, cough, very nervous, wakeful, perspiration, another set of remedies required. Fourth day delirium, different remedies. Fifth day patient is dead and no remedies required.

I am aware that I have painted this picture black, but I have seen just this happen, and I wish to ask in all candor which patient has the best chance for his life, the one who has his disease correctly diagnosed from the start, and is under the care of a physician who bends every effort to forestall those fatal symptoms that he knows do occur in the history of the disease, or the one whose disease is not diagnosed and the medical attendant follows along behind treating the symptoms after they arise? Should he do otherwise he will be applying "regular" principles, and the

results obtained should be credited to the regular profession.

Let me exhort all who proclaim themselves pathists to follow each his own respective pathy or creed vigorously like a man, or if you deem your pathy insufficient, then drop it altogether and come into the regular profession body and soul. The profession is broad enough to furnish you ample scope for your faculties, and will receive you with open arms when you come with an honest purpose, but be honest. Be one or be the other, but do not practice one and give the credit to the other.

Let "regulars" employ every opportunity to proclaim themselves such. Never allow the word "pathy" to sully your garments or tarnish your fair name. Repudiate it whenever, wherever and by whomsoever applied. Do it with kindness and dignity, and neither you nor the profession will suffer thereby.

While there are many good, ample and sufficient reasons why a regular should not call an irregular to consult with him; still if the patient has been employing an irregular and needs your counsel, it seems to me your duty is plain, for as the regular profession embraces everything under the sun that can help the patient, it certainly embraces all the pathist is doing and whatever is to be done besides, and if the pathist will give you due credit for your advice and you can agree pathologically, you may do the patient good and still preserve your professional dignity.

SOCIETY PROCEEDINGS.

The Quarantine Convention of the South Atlantic and Gulf States.

The Program outlined was Changed.

The Convention Decided to Discuss the Questions of State and National Quarantine Before Anything Else.

The quarantine convention of the South Atlantic and Gulf States convened in the Princess Theater, Mobile, Ala., at 10:40 A.M., Wednesday, February 9.

At that hour Dr. W. H. SANDERS, State Health Officer, requested all the members of the executive committee to take seats upon the stage.

This request was acceded to by those present, and when Governor Johnston ascended the stage he was greeted with applause.

Dr. Sanders then, as chairman of the executive committee, nominated Governor Joseph F. Johnston for temporary chairman. This nomination was greeted with applause, and was adopted.

Governor Johnston took the chair and announced that the convention would be opened with prayer by Rev. J. R. Burgett, D.D., pastor of the Government Street Presbyterian Church.

At the conclusion of Dr. Burgett's prayer Governor Johnston said in substance:

"It is hardly necessary for me to say that the people of this State feel gratified to have you here, whether you come from our own State or from other States of this grand Union; and so long as this fair city stands here by the sea, so long will Alabama welcome the representatives of other States within her borders. We are glad to have you here—representatives of Texas, Louisiana, Florida, Georgia, the Carolinas and other States. If an armed enemy threatened our shores, it is to those States adjoining us that we would turn for aid. When we come to consider the entrance of an enemy worse than an armed foe, it is to these States that we look for aid. This insidious enemy threatens our lives, our commerce and business interests, and we are here to devise the best means of keeping out this disease. I am not going to lengthen these proceedings by making a speech, but will turn the business over to the convention believing that methods can be devised

whereby the States and National government, each in its own proper sphere, can control these matters of quarantine."

On motion of Dr. Sanders, Dr. H. A. Moody, was elected temporary secretary.

Dr. Sanders moved the appointment of a committee on credentials to consist of one from each State; adopted.

Mr. John B. Knox of Anniston moved that the list of States be called and the delegates send up their names to the secretary; adopted.

The secretary then called the roll of States, and the delegates sent up their names to the secretary.

Governor Johnston then appointed the following committee on credentials:

Hon. P. W. Meldrim of Georgia, Dr. S. R. Olliphant of Louisiana, Dr. H. A. Moody of Alabama, Dr. J. H. Purnell of Mississippi, Dr. R. P. Daniel of Florida, Dr. H. B. Horlbeck of South Carolina.

Dr. Sanders moved the appointment of a committee on permanent organization, to consist of one member from each State; adopted.

Governor Johnston appointed the following committee:

Dr. W. H. Sanders of Alabama, Mayor C. A. Collier of Atlanta, Dr. N. L. Clarke of Mississippi, Dr. Bat Smith of Texas, Dr. Edmond Souchon of Louisiana, Dr. H. B. Horlbeck of South Carolina, Hon. J. E. Grady, J. L. Ludlow of North Carolina.

On motion a recess of fifteen minutes was taken to allow the committees to formulate their reports.

Dr. Edmond Souchon of New Orleans, read the following majority report of the committee on permanent organizations:

Dr. C. P. Wilkinson of Louisiana, president; Dr. R. P. Daniels of Florida, J. L. Ludlow of North Carolina, Dr. H. B. Horlbeck of South Carolina, Dr. Bat Smith of Texas, Dr. O. B. Quinn of Mississippi, Hon. Leslie E. Brooks of Alabama, Charles Chassignac of Louisiana, Clarence Knowles of Georgia, vice presidents; Dr. H. A. Moody, secretary.

The committee also recommended a change in the program so that the first matters of discussion be the subjects of State and National quarantine, and that all questions relating to these matters outlined in the program proposed by the executive committee be considered together.

Dr. Sanders submitted a minority report urging that the program remain as outlined. He said it had been drawn up carefully after a good deal of correspondence and those matters placed first were the bedrock upon which the whole subject of quarantine is based. He urged that the program be adhered to.

Dr. Horlbeck of South Carolina, held that the matters of State and National quarantine were the bedrock of the matters for the discussion of which the convention has been called.

The majority report was adopted as to permanent officers, and Dr. Wilkinson was called to the stage. As he took his seat he was applauded.

He thanked the convention for the honor conferred upon him.

He then called for the report of the committee on credentials, and Dr. Moody, chairman of that committee, reported that it would be several hours before a roster could be completed, and that those present be recognized as *prima facie* delegates until the roll is complete.

There being no objection, it was so ordered.

It was moved the majority report be adopted.

Dr. Sanders moved a substitution of the minority report for the majority report.

Mayor Collier of Atlanta said that this convention met for business and we want to get to business at once. The whole country recognizes that the great practical question to be considered by this convention is the question of National and State quarantine. The program has been lengthened out over a number of topics that will take up an entire week or more. Why, the Senate of the United States has been asked to stop its deliberation till this question can be passed on by this convention. One of the subjects is "What constitutes an original package?" Why, the supreme court of the United States has not been able to settle that question. Let us get down to the discussion of practical questions and leave such topics for experts.

The vote was then taken on the substitution of the minority for the majority report, and the motion to substitute was lost. The majority report was adopted by a large majority.

Dr. Souchon, chairman of the committee on permanent organization, then read the order of business as to consideration of the program: Nos. 1, 2, 3, 4, 12, 29 and 36, then to follow the program as outlined.

It was moved and adopted that papers be limited to twenty minutes and discussion to five minutes to each speaker, and this rule be inviolable.

Hon. HANNIS TAYLOR then read the following paper:

QUARANTINE WITH REFERENCE TO INTERNATIONAL RIGHTS AND INTERESTS.

To me has been assigned the duty of opening the deliberations of this convention by a brief dissertation upon "Quarantine with reference to international rights and interests." I find from investigation that the plague, yellow fever, and Asiatic cholera have been the two great spreading diseases, which have been the main causes of the precautions which modern nations have been forced to take to protect themselves against epidemic invasions.

If we seek the beginnings of the history of quarantine we find them in the precautions taken by Venice, Genoa and Marseilles, in the fourteenth and fifteenth centuries, to prevent the introduction and spread within their bounds of the plague, a disease coming from the East. When we turn our eyes to the new world, we find, apart from occasional visitations of cholera, the chief object of quarantine on the American continent and adjacent islands has been to prevent the importation of yellow fever from Brazilian, West Indian and Peruvian ports, where it exists in an epidemic form. We of the South have special reasons to know quarantine for us means something to protect us from the invasion marching mainly but not exclusively from the harbors of Havana and Rio de Janeiro. I remember that the late Dr. Cochran, who in his day, was looked upon as a master of the subject of public hygiene, told me many years ago that the place for us to fight yellow fever was in the harbor of Havana. He said that if he only had the power so to purge that cesspool of filth and corruption as to put it in a sanitary condition, he believed that yellow fever could be strangled in its most dangerous lair. With that accomplished, as he thought it could be, by efficient government in Cuba, he said that the protection of our Southern ports against the invasions of yellow fever would become comparatively easy. In the light of these plain facts, it is not hard to demonstrate that every nation has a direct and urgent interest in the quarantine regulations of a neighboring State, especially when that neighboring State is the hot bed of a malignant and contagious endemic disease that is liable at any moment to cross the national boundaries. In our own case the harbor of Havana is the object lesson to which we naturally turn for illustration. I have been informed by an eminent member of our consular service, who resided there for nearly twenty years, that as an engineering problem, nothing is easier than the cutting of a canal a few miles long that would afford such an outlet to the pent-up waters at Havana as would render that harbor one of the purest in the new world. Considering that that focus of infection is only a hundred miles from our coast, as the crow flies, certainly the people of the Southern country have a direct and urgent interest that should enable us to demand that that port be put in a sanitary condition at an early day. But, when we come to consider the right, under the laws of nations, of one nation to demand of another the doing of such thing, we find nothing but a vacuum. In that particular, international law is necessarily defective by reason of the fact that each nation's system of quarantine is one of those matters of internal concern over which each sovereign state has supreme and exclusive jurisdiction. If you have a neighbor in your own town who keeps on the premises adjoining your own, some offensive or other thing that imperils the health and life of your family, you can so deal with him under the provisions of municipal law that he will be compelled to remove it. But, if a nation has a neighbor that keeps up a nuisance that imperils the lives, not only of its own people, but of all neighboring peoples, international law provides no remedy whatever. You can not invade the territory of the offending state, in order to force it to discharge its duty to itself and to humanity.

You can not send even a sanitary inspector within the limits of the infected state to study the disease in its lair, without its consent. In all such matters you can only fall back upon what is called the comity of nations. Only through international courtesy can we examine through officials the sanitary conditions of foreign ports that menace us most. Only through such courtesy are we able to take such precautions as we are now taking with the aid of our consular service in foreign lands. Because, as you all know, every consul's power to act in any foreign country depends upon his exequatur that may be withdrawn at any time. So when viewed from an international standpoint every nation has a direct interest in the quarantine system of every other nation; but no nation has any right whatever as a matter of international law, to interfere with, regulate or control, or even to pry into the quarantine system of another state.

Of course it would be perfectly proper and in order for all

nations to unite in a Congress with the view of dealing with the entire subject of quarantine from an international point of view. There is no reason why there should not be quarantine union between the nations just as there is a postal union. If there could only be a general agreement in this matter, that each state owes a direct obligation to every other state that must be discharged under a uniform system of rules to be rigidly enforced by all, a wonderful advance could no doubt be made in the right direction. But as I have been called upon only to preface this discussion, I do not feel at liberty to trespass longer upon you.

DISCUSSION.

Hon. LESLIE E. BROOKS said that the progress in ocean traffic had made an intelligent and rigid system of quarantine necessary. He said that this was due to the fact that steamships could leave the shores of an infected country and reach our shores before the known period of incubation had passed. Quarantine was necessary as carrying out the law of self-defense. Quarantine is a conservative means to conserve the self-preservation. This country has a right, if other nations fail, to fall back on the right of self-preservation and quarantine against any other nation where infection exists.

Hon. LESLIE B. SHELDON moved that such as desired be allowed to speak from their seats on the floor; adopted.

Mr. P. J. HAMILTON said there are three things about yellow fever. What is it, how to treat it, and how to prevent it.

A DELEGATE—Are you speaking to the subject, which is international quarantine?

Mr. HAMILTON—Yes, sir; we can prevent it by international quarantine. The nations of Europe are endeavoring to meet the question by some agreement between them, something in the nature of a treaty. Mobile and New Orleans have inaugurated the proper method. They have placed medical agents at infected ports, who report any danger at once. That is the way the United States can further the international quarantine. Let the United States take the lead in some convention with those countries south of us and let this matter of medical agents be perfected. There is one thing about yellow fever, and that is that prevention is better than cure.

Dr. H. M. CARTER also spoke on the subject. He said that in most of the ports of Cuba the United States had sanitary medical inspectors, and that international law is no bar to United States officials serving in foreign ports.

Hon. R. H. CLARKE said this convention ought to take some action looking to an application to the Government for the maintenance of a corps of medical experts in those foreign yellow fever ports. He moved the appointment of a committee of five medical gentlemen to name the yellow fever ports at which medical agents should be stationed, and to call the attention of Congress to the matter, as well as the holding of an international quarantine convention.

Dr. HAMILTON of Chicago, spoke of what had been done in Europe by the nations in relation to quarantine, and of the Pan-American Medical Congress at Washington.

The committee on permanent organization reported the hours of business as follows: From 9 A. M. to 1 P. M.; 2:30 P. M. to 5 P. M.; 7 P. M. to adjournment.

The convention then recessed till 2:30 P. M.

AFTERNOON SESSION.

The chair called the convention to order after recess and announced the following committee to recommend appointment of medical inspectors at various foreign ports: Dr. John B. Hamilton of Illinois, Dr. S. R. Olliphant of Louisiana, Dr. H. R. Carter of the Marine Hospital Service, Dr. R. P. Daniel of Florida, and Mr. P. J. Hamilton of Mobile.

FEDERAL AND STATE POWERS AS TO QUARANTINE.

Hon. EDWARD H. FARRAR then read a paper on "Federal and State Powers as to Quarantine." He said the line of demarcation between the two had been the battle ground of lawyers, judges and politicians for years past. He then discussed at length the legal aspect of the question, and cited the creation of the general government, which he said could have no power, except expressed in the instrument showing the grant of powers to it by the States, and referred to the adoption of the tenth amendment. The speaker discussed the relations of the States to the general government, and said that matters of quarantine were reserved to the States unless they had been expressly relegated to the general government. He spoke of the different factions in construing the constitution of the United States, and cited a large number of legal authorities and opinions of Chief Justices Marshall and Story and other justices of the United States supreme court.

Quarantine laws are health laws and belong to the police power, which have never been taken from the State, and in

which rest the protection of the health, life, well-being and prosperity of the people. He held that if the State did not pass laws to prohibit nuisances, the spread of disinfection, the punishment of incendiarism, murder, assaults, etc., congress can not pass such laws. He cited a number of authorities to show that the police powers of the States had never been delegated to the general government.

He held that as quarantine laws had been classed as part of the police powers of the State, and that such police power had never been delegated to the Congress, therefore there was no power implied or expressed in Congress to pass quarantine laws.

If quarantine laws control commerce between states and nations, Congress can deal with them; but if they simply affect commerce, then the Congress has nothing to do with them, especially if they are bona fide health laws; I do not mean shotgun quarantine, nor those which prevent a train from passing from one locality through another. I believe that the enactment of quarantine laws is therefore reserved to the States.

He cited a number of legal opinions and authority on the subject.

He held that Congress had no power to pass an exclusive quarantine act, regulating both maritime and internal quarantine, and the movements of persons and goods within the limits of a State. From 1799 down, the rights of the States to pass quarantine laws had been recognized, and if this power had been specially reserved to Congress, why was it that Congress had continually recognized the right of the States to pass such laws? He declared the State sovereign and deprecated the drift toward centralization and paternalism.

The paper was a very exhaustive legal argument in favor of State quarantine. The reader was called down by the time limit.

Unanimous consent was asked for the reader to continue, but objection was made.

Hon. R. H. CLARKE then moved reconsideration of the provision limiting readers of papers to twenty minutes, which was adopted.

On motion, Mr. Farrar was then invited to continue his paper.

He thanked the convention for the courtesy and was roundly applauded.

During the continuance of his argument he was frequently interrupted by applause.

Hon. R. H. CLARKE then spoke on the paper. This is a convention gathered for suggesting the best means of keeping yellow fever out of this country. No sooner does an epidemic of yellow fever break out than we begin to call on the government for aid. We want money, camps, rations and other things, but still we say to it "hands off." Such a state of things can scarcely exist. There are two divisions of quarantine. One is a boundary quarantine, and the question is, has the general government the right to say to a vessel that it shall not enter any port or proceed up any river or harbor. The government has the power to turn back from any harbor of this country men and merchandise. He argued that the general government had the power to do these things. Before the completion of the argument the time limit expired.

There was a motion to extend the limit, but Mr. Clarke asked that such motion be not put.

DISCUSSION.

Mr. HARRY PILLANS of Mobile said the paper did not raise the mooted question as to whether the State or federal authority was best to settle the matter of quarantine. He said that what is police power is yet to be determined. I have failed to discover an epidemic of disease this summer, but we did have an epidemic of fear and cowardice. The police power is one that can be reposed in a safe government when it is reasonably exercised. The enthusiasm of our boards of health has carried them far beyond their power. The Governor of the State has had the hardihood to say that no citizen should come out of Atlanta, a place not infected, and enter the State of Alabama. I have never heard of a more despotic ruling. There was absolutely no law in right or reason for such action. He spoke of the habit of cities or towns to quarantine towns between them and infected cities unless those towns did quarantine the infected city or town.

Dr. W. H. SANDERS interrupted to say that no quarantine was declared until there was a case of yellow fever declared in Atlanta.

Mr. PILLANS said it remained a fact, however, that many towns did threaten to quarantine Atlanta unless she did as many other inhuman cities did, shut her doors against fleeing women and children.

Captain J. M. FALKNER said the Louisville and Nashville had lost thousands of dollars and he wanted to acquit the boards of health of wrong-doing. These medical gentlemen

tell us that yellow fever does not originate in this country, then why stand here and shout about States' rights? The disease comes from without and Congress having the power to regulate the foreign commerce, she should have the power to keep this foreign enemy out. The announcement of a case of yellow fever in Mobile to-night would cause a greater stampede than the invasion of the entire Spanish army. Continuing, the speaker contended that the disease being a foreign importation, the general government should be charged with the power to resist such an invasion. It is the duty of Congress to resist the invasion of this disease as it would resist the invasion of a foreign army.

So long as Havana is infected with yellow fever all vessels coming from Havana, whether they have sickness on board or not, should be treated as infected and held in quarantine a sufficient time to preclude the possibility of infection. Congress should furnish all the money necessary and the men and plants necessary to keep out this disease. With the ports bidding for commerce and no uniformity of quarantine, it is not unlikely that we shall have a recurrence of the experiences of the past summer.

Health Commissioner REYNOLDS of Chicago, said it was the hope of Mayor Carter H. Harrison of Chicago, that some action would be taken at this convention to perfect the quarantine laws. He said that Chicago was interested in the commercial side of the question and that the producers all over the country were interested in the deliberations of this convention.

W. F. VANDIVER of Montgomery, said he did not think the question of States' rights was pertinent. That was a political question and this is not a political convention. You can not expect reason from a lot of terror-stricken people any more than you can from a mob. We had an epidemic in 1873 that was fraught with death, and plenty of it, and in 1897 the death rate was not so great, but there was more excitement and more loss. He related several experiences of the past summer and said that this convention should say to the United States that we charge you with keeping out the disease and if you let it get in we want you to hunt it out.

In answer to a question, he said he would place the matter in the hands of the National Government.

T. G. BUSH of Anniston, then spoke. He said he was the fourth speaker in that immediate circle, which is proof of the spirit that moves us. He told two anecdotes and said that he believed the question had been settled. Once he was a member of the legislature, and whenever some members did not want to vote for a question they would say it was unconstitutional, but he told them the supreme court would settle that. He favored relegating the matter to the general government. He did not come as a mendicant, but he asked it as a right, as a child of the Government. We want uniformity. My railroad experience is that for two weeks we could not turn a wheel. We left Anniston, went through Atlanta and then came to New York; but on our return we came around Atlanta, but the quarantine officer refused to let me in. We want no repetition of this. We want common sense. We want uniformity.

Dr. BAT SMITH of Texas, stated that Dr. Warren Stone said yellow fever was indigenous to New Orleans. You are hunting the focus of the disease in foreign ports, but if you will go around and make the people clean their city and then you will destroy the fever. A scavenger in Mobile or New Orleans is worth more than a health officer.

Dr. CHARLES CHASSAIGNAC called the gentleman to order and said the sanitary condition of New Orleans is not under discussion, and she is abundantly able to take care of herself.

The chair then read the Committee on rights of suffrage of delegates as follows:

Collier of Georgia, Clarke of Alabama, Grady of Florida, Corrie of Louisiana, Taylor of Mississippi, Ludlow of North Carolina, Horlbeck of South Carolina, Smith of Texas, McShane of Maryland, Hamilton of Illinois, Wingate of Wisconsin, Holloway of Kentucky, Robinson of New York.

Dr. ROBBINS of Mississippi, disclaimed any reflection on the Mississippi State Board of Health in his remarks at the morning session.

DR. ROBINSON'S PAPER.

Dr. S. A. ROBINSON of New York, then spoke on the subject. He said quarantine was a common cause against a common foe, and alluded to a private opinion submitted by him, which is as follows:

Influenced by the effects of cholera upon the business and social life of New York in 1892, the New York Board of Trade and Transportation then made a pretty thorough investigation of quarantine, and recommended the immediate establishment of a national quarantine system. Congress passed an act, en-

titled "An act granting additional quarantine powers and imposing additional duties upon the marine-hospital service," which was approved Feb. 15, 1893. Believing the proper administration of this act would exclude diseases quarantined against, or confine them to where they first appeared and promptly eradicate them, we felt secure. Now, influenced by what Southern commerce and society suffered from yellow fever in 1897, we are collecting information regarding quarantine and the prevention of disease in general.

Being a member of the committee selected by the board for that purpose, and thinking I could learn more from the gentlemen composing this convention than from any other source I am, thanks to your courtesy, here for that purpose. We are receiving a great deal of valuable information, all of which will be at your service as soon as it can be compiled and published, but we are especially desirous for your advice and assistance, and will in return do what we can to aid you in securing legislation that will best protect the people and the business of our entire country.

I think that quarantine, or disease limiting and preventing authority, must be uniform in order to be most effective. Not uniform in methods, for conditions vary and methods must meet conditions, but uniform in spirit and power. The idea that forty-five systems of quarantine (one for each State) could best protect the people of the United States seems preposterous. To thoroughly protect our entire population such authority and regulations must be National.

To ascertain the validity of the contention that the federal government can not constitutionally establish and maintain a national quarantine system, the New York Board of Trade and Transportation decided to consult one of the best authorities on constitutional law, and selecting W. B. Hornblower, obtained the following opinion:

Hornblower, Byrne, Taylor & Miller, No. 30 Broad Street, New York, Jan. 24, 1898.

Frank S. Gardner, Esq., Secretary New York Board of Trade and Transportation:

Dear Sir:—In accordance with your request made some time ago, for my views on the subject of national quarantine, I beg to say that I have been so occupied during the past few weeks in court work, that I have had no opportunity until recently to examine the papers you have sent me and to give the matter consideration.

As to the constitutional power of Congress to establish a department of public health and to assume control of a general system of quarantine throughout the country, I have no doubt. I do not base this power, however, upon the "general welfare" clause of the constitution. To construe that clause of the constitution so as to cover this subject would authorize the assumption by Congress of any powers which at any time it deemed for the general welfare of the public at large and would absolutely abrogate the constitutional amendment which provides that:

"The powers not delegated to the United States by the constitution, nor prohibited by it to the States, are reserved to the States respectively or to the people." (Tenth amendment to the Constitution.)

I am of opinion, however, that under the clause of the constitution authorizing Congress "to regulate commerce with foreign nations, and among the several States, and with the Indian tribes" (Section 8, Article 1), a national system of quarantine can be established and maintained.

So far as concerns quarantine regulations affecting our international commerce, there can be no doubt that the present State regulations are lawful merely because Congress chooses to allow them to remain in force and are lawful only so long as Congress chooses. I so understand the decisions of the United States supreme court. These quarantine regulations operate as restrictions upon foreign commerce and as such can be at any time set aside by federal legislation, and Congress can itself assume jurisdiction over this subject.

The right to regulate commerce "among the several States" is as broad as the right to regulate commerce "with foreign nations." It follows, therefore, that Congress has the same right to establish and enforce quarantine regulations, as affecting interstate commerce, that it has to make and enforce quarantine regulations as to foreign commerce. With regard to vessels in the coasting trade, arriving at one port from another port of the United States, the same regulations can, of course, be easily applied that are applied to vessels arriving from foreign ports. The practical difficulty arises in the case of interstate communication by land. I have no doubt of the right of Congress to establish quarantine regulations which shall affect all railroads carrying passengers or freight from one State to another, just as by the interstate commerce acts Congress has assumed jurisdiction over the railroads with regard to rates,

etc. As practically all railroads do an interstate business, directly or indirectly, by carrying passengers and freight in transit from one State to another, quarantine regulations could, therefore, be established over practically all railroads in the United States. Such a system of railroad quarantine would necessitate and would authorize the establishment of a United States quarantine station in the principal commercial city of every State in the Union, and this quarantine station could, it seems to me, effectively control the quarantine regulations of the entire State, co-operating, of course, with the local authorities as far as practicable. I do not see why a system could not be worked out on this line which would be efficient and satisfactory.

As to the desirability of a national quarantine, it seems to me there can be no serious room for discussion. Conceding the right of the government to interfere with the liberty of the citizen and with his rights of property, so far as may be necessary for the protection of the public health, the only question is, whether it is more expedient that this right should be exercised by the local government or by the State government, than by the general government? It seems to me that a uniform system administered by national officers is the only safe and rational method of administering this branch of government. Of course, the tremendous powers imposed upon quarantine officers are open to abuse, but such abuse by national officers would have a wider publicity and be subject to more direct remedial legislation than would the petty tyranny of local officers, especially where the sufferers from such tyranny would usually be non-residents of the locality where the officers exercise their authority. As quarantine is of necessity an interference with commerce, it seems to me that it is peculiarly a matter within the province of federal legislation.

Trusting that I have sufficiently answered your inquiries, I remain yours very truly,

W. B. HORNBLOWER.

Perhaps nothing marks the progress of modern civilization with more precision than the improvements in preventive medicine and hygiene. If we teach our people the value of these improvements they will demand that their legislators give them the benefit of them, and every true citizen of our country will welcome and promote the best possible system of quarantine.

Thomas Jefferson, then President, in a communication to Congress on the state of the Union in 1804, protested against the adoption of a code of laws to prevent the introduction of yellow fever. Our people have learned a great deal since 1804, and the response which they would make to such a protest by their President today would clearly indicate it. When they know what science can do to exclude and prevent disease they will be wise enough to unite in a determined and persistent effort—each for all and all for each—to secure every advantage it can confer, and will demand that safety and not sentiment shall decide and govern all that pertains to quarantine.

Dr. BAT SMITH of Texas said that Texas wanted to place herself on record as desiring to police her own borders. She has the men and she has the means. She is willing to meet the Marine-Hospital Service half way, but she does not want federal interference and is not going to stand it.

A DELEGATE—Did not the Governor of Texas ask the aid of the federal government to stamp out smallpox at Eagle Pass?

Dr. SMITH—Who was Governor?

THE DELEGATE—Governor Hogg.

Dr. SMITH—Oh, he was not responsible.

Hon. W. A. KAY of Georgia also spoke on the subject. He said the legislature of Georgia called on the federal government because they recognized it was a condition that Georgia and her sister States could not meet. You may pooh-pooh shotgun quarantine, but you must have a stronger power to put it down. He favored going to the general government to get the assistance so badly needed.

Mr. JOHN B. KNOX of Anniston spoke as follows:

Mr. Chairman: I had not intended to take any part in the discussion of the topic now before the convention, but since hearing the elaborate written argument against the constitutionality of the proposed legislation by the federal government on this subject, I feel impelled to say something upon the legal question involved.

I was surprised to hear it asserted by the honorable gentleman (Mr. Farrar) that the federal government as now administered is not a government by the people, and that the only government where the voice of the people is recognized is the government by the States.

Mr. Chairman, I do not sympathize with this effort to excite the prejudice of this convention against the national government. I have always been taught to believe that the system of government under which we live is the best ever conceived. It was the product to a large extent of Southern intellect and Southern statesmanship. In its conception and development

the country had the benefit of the wisdom, experience and intellect of Madison, Jefferson, Washington, Henry and a host of others, who labored together to perfect the finest system of popular government that the world ever saw, and I think that no prejudice against our form of government can be aroused before a Southern audience by any attack upon the wisdom of the fathers in its formation.

Mr. Chairman, the constitution of the United States invests the national government with the absolute power to regulate commerce between the States and with foreign nations. This power is granted to the general government by the States. It is not granted with any proviso that it shall not be so exercised as to conflict with the police regulations of the States, and to become inoperative when it does; but it is absolute and imperative, and when properly exercised the powers of the States, so far as their police regulations are concerned, must give way.

I will not discuss the proposition that the State quarantines, not to say the shotgun quarantines in force in several of the Southern states during the year 1897, interfered with interstate commerce. To a large extent everybody knows that it not only interfered with interstate commerce, but absolutely destroyed it.

The honorable gentleman from Louisiana (Mr. Farrar) refers to two decisions of the supreme court of the United States which he condemns in the most intemperate terms. I listened with great interest to the reading of his paper and I failed to hear any opinion, or, if you please, any dictum, from the supreme court of the United States or any other court to the effect that the federal government had not the power to enact a general quarantine law.

On the contrary, I beg to call your attention to two decisions of that court, which seem to hold directly to the opposite.

The honorable gentleman contended before us with great earnestness that the federal government could only act in aid of the State government. My understanding of the law is just the reverse. Where the federal government has jurisdiction and it has been actually exercised, it is supreme and not subservient to the State regulations.

In the leading case of Peete vs. Morgan (19 U. S., 581) the supreme court of the United States, in passing upon the validity of State quarantine regulations, says: "They are enacted for the sole purpose of preserving the public health and if they injuriously affect commerce Congress, under the power to regulate it, may control them."

And again in a still later case, Morgan Steamship Company vs., Louisiana (118 U. S., 465), Mr. Justice Miller speaking for the court says: "Whenever Congress shall undertake to provide a general system of quarantine, all the State laws inconsistent with said enactment will be abrogated, but until this is done the laws of the State on the subject are valid."

The honorable gentleman from Louisiana (Mr. Farrar) does not attempt to answer these decisions. He says of the first that it is mere "judicial slop," and of the other, that it is mere "judicial gush." Mr. Chairman, both of these cases are announced as the opinion of the court, and the second opinion was delivered by (Mr. Justice Miller) one of the ablest judges who has sat upon that bench. And I submit, therefore, that the effect of these decisions is not to be destroyed, either by abuse of the court, or by the contempt expressed by the learned gentleman for the justices who wrote the opinions. And I may say, in conclusion, Mr. Chairman, that the question of the constitutionality of a federal quarantine law has recently received very careful consideration from a committee of the United States Senate, upon which were some of the best lawyers in the Senate, and a report was made, practically unanimous, sustaining the constitutionality of the proposed legislation.

Mr. NORMAN WALKER of New Orleans, cited the report of the committee referred to by Mr. Knox.

Dr. ROBBINS of Vicksburg, Miss., said that the sentiments expressed against the General Government found no lodgment in the hearts of the people of Mississippi. They had seen the States utterly powerless to protect their citizens, and he for one had come here to appeal to the General Government to do that which the States are powerless to do.

Mayor COLLIER of Atlanta, protested against the sentiments expressed against the General Government, which he said is "my country." He said that he read of one board of health in Alabama which by a vote of four to three refused to admit ice, and another a carboy of carbolic acid. He said the system of quarantine in vogue last summer was a disgrace to civilization.

Mr. FARRAR replied and said he never denied the right of the Federal Government to pass quarantine laws such as Mr. Clarke cited. He replied briefly and pointedly to the arguments put forward by the other speakers and showed his familiarity of the legal aspect of the State and Federal Government.

Hon. HANNIS TAYLOR spoke upon the subject and said that the State quarantines had been broken down and routed and in Louisiana the Board of Health run out of office by an indignant people. He argued that the power to enact quarantine laws was reposed in Congress and said that the question was how best to formulate a law that would meet the desired end and at the same time reserve to both the State and Federal Governments their legitimate powers.

Dr. SANDERS protested against Mr. Taylor's statement that State quarantines had been a failure.

Mr. TAYLOR said he did not mean the remark in that light. He meant that the boards of health as a whole had been routed.

Dr. SANDERS, continuing, defended the boards of health.

Dr. ROBBINS, of Mississippi, asked if the people did not set at defiance the State boards of health. He said that such was the case in his State.

Mr. KNOWLES, of Atlanta, offered a resolution as follows:

WHEREAS, The experience of last year during the prevalence of yellow fever was sufficient to demonstrate the inefficiency of State, county and municipal quarantine regulations, as well as the resultant disastrous effect on commerce, travel, and the public comfort and safety; therefore, it is the sense of the convention that congress should enact such legislation as will result in the establishment of a national uniform system of quarantine with due regard to the rights of the various States.

It is not the purpose of this convention to endorse any plan, system or legislation now proposed, but simply to place on record its belief in the necessity for uniformity and such enforcement as is only possible under national supervision, leaving the plan and its details to our representatives in congress.

Dr. HORLBRECK, of South Carolina, protested against the criticism against State boards, and said that the Board of his State had kept the disease out of that State through several epidemics. He thought they ought to find out all about the disease. There are plenty of laws about quarantine, and all they need is to be enforced.

Mr. E. L. RUSSELL cited the practical experience in the management of the Mobile & Ohio railroad during the recent yellow fever, stating that the receipts for the three months exceeded any similar period in the history of the road; that no case of fever was carried beyond Whistler, showing that, with harmony, the States could manage affairs themselves.

Ex-Lieutenant Governor SHAND, of Mississippi, defended the State Board of Health of Mississippi.

Dr. ROBBINS asked if members of the board had not continued to proclaim to the world that the fever at Ocean Springs was dengue.

Dr. HARALSON replied and stated what took place at Ocean Springs relative to the disease there.

The chair called the speakers to order time and again, saying this was no debating society for the adjustment of personal questions.

President T. G. BUSH, of the Mobile & Birmingham railroad, gave his experience in the running of that road. He said he had to deal with the board of health of Dallas. The first thing they did was to cut off thirty-two miles of his road, declaring that everything that passed over the line into Clarke county was infected and could not come back. Fumigation was no good.

Hon. R. H. CLARKE said that if the State of Alabama would appropriate money enough to run the quarantine plant at Fort Morgan he would be satisfied to have the present board conduct that quarantine.

A telegram of greeting from the Tennessee Board of Health and promising co-operation was read.

(To be continued.)

New Jersey State Sanitary Association.

The meeting of this Association was held at Lakewood, Dec. 10, 1897. The President, Mr. JAMES OWEN, C.E., of Montclair, called the members to order at 3 P.M.

Dr. JOSEPH W. STICKLER of Orange, Chairman of the Committee on Inspection of Factories, read his report.

He inspected the factories of Orange, Newark and Paterson and, as a result, suggested these points to be borne in mind in such work: Site, drainage, condition of cellars; are rooms occupied day and night; are rooms overcrowded; ventilation; plumbing; condition of cesspools and water-closets; cisterns, size and condition; condition of drinking water; temperature of working rooms; condition of the atmosphere in rooms; clothing worn by operatives; environments; subsoil; wells, their condition; height of ceilings; sanitary defects around the factory; food and drink of operatives; amount of rest allowed employees; personal habits of operatives; the state of the nutrition and general health of the operatives. Dr. Benjamin of Jersey City, and Dr. Braymer of Camden and Dr. Baldwin of Newark inspected the factories of their respective

cities and concur with me as to the importance of paying special attention to the above points, and also that many of the buildings are in good sanitary condition, others are in an insanitary state.

A careful consideration of the factory laws, etc., can not fail to convince one of the fact that ample provision has been made for the safety and health of those who work there. If clause x of supplement to an act entitled "A general act relating to factories and work shops, and the employment, safety, health and work hours of operatives, approved April 7, 1885, were the only legal enactment appearing on the pages of the statute book and were faithfully and conscientiously carried into effect in every instance by the inspectors appointed by the State, no factory within the borders would be likely to be justly criticised. It is fair to say that we found many of the factories in the best condition, but some indicated that the inspectors must have failed to carry out their instructions. In either case there is good ground for adverse criticism. Dr. Torrop of England says: "Factory work is not so excessively laborious; it is the heat, impurity, and dust-laden atmosphere that injures health. The promising child of ten degenerates into the lean and sallow person of thirteen and this process is continued until a whole population has been stunted, and thus factory life becomes a source of danger to the future of England. In addition to the loss of physique, it is instructive to note the deterioration of personal appearance. Out of 2000 children under notice, only sixteen could be described as handsome, and of those the larger proportion were girls from Ireland." It seems to me that what is true of England must be equally true of America. For this reason inspectors should be careful to enforce the laws for the protection of factory employees. Inspectors should be men who understand the effects of any given employment upon the health of those engaged in it, and to this end it is essential to understand the conditions and circumstances connected with it, and these are found to be almost as numerous as the occupations themselves (Arlidge). Again, it should be known that hereditary influence as an accidental condition, coupled with the social status of an employment, has a tendency to perpetuate physical defects and disorders engendered by the occupation (Arlidge). "Another fact is that large wages have to be given in various offensive, unhealthy and dangerous trades; and as may be supposed the workmen attracted to them belong chiefly to the reckless class, broken-down characters in the lower stratum of society who are willing to lead a short and merry life."

Experience has shown to this grade of laborers that the obnoxious work they carry on, plus the possession of means for self-indulgence, operates as an inducement to intemperance, vicious habits, neglect of home cleanliness, comfort and health. Again, season trades are fluctuating; periods of active operation are followed by stagnation. It is manifest that this must affect, deleteriously, the health of the employed. It should also be understood that an insistence upon sanitation in factories means the protection of the workman; and that means one way of removing the antagonism between capital and labor. Dr. Guy, in making an analysis of the official monthly tables to discover the "influence of employments upon health," made the following statements: "The ratio of cases of pulmonary consumption to other diseases is highest where the amount of exertion is least, and lowest where it is highest; and the intermediate degree of exertion presents an intermediate ratio. The age at which consumption makes its attack is earlier in employments requiring little exertion than in those requiring more, and in those requiring moderate exertion than in those demanding a great effort. The average of deaths is lowest where there is least exertion, but highest where the exertion is intermediate between the extremes. The class of outdoor occupations requiring moderate exertion presents a higher percentage proportion of deaths under 40, and a corresponding loss of young men. Sedentary employments and those requiring little exertion are more unfavorable to adult and middle life, but more favorable to old age; on the other hand employments requiring great exertion are unfavorable to youth and longevity, but favorable to middle age. Employments with little exertion prove fatal by inducing an excess of consumption early in life; those requiring great exertion by occasioning other diseases of the air-passages and lungs, toward the commencement of old age."

Dr. Greenhow sums up: In proportion as the male and female population are severally attracted to indoor branches of industry, in such proportion, other things being equal, their respective death rates by phthisis are increased. Racial peculiarities have much to do with the effect of labor on health. Attention has been called to the fact that an occupation or a manufactory recruited with Celtic Irish workers may be expected to have a higher rate of mortality than would obtain if

Anglo-Saxon workers are employed. These matters should engage the attention of the men whose duty it is to inspect the factories of our State. When we are reminded that in the factories of New Jersey today, 50,848 persons are working, and that the health of this large army actually depends upon the well-directed efforts of our State factory inspectors, and upon wise and comprehensive legislation, I think you all will agree that our time has been well spent. No man who is unfaithful or limited in his knowledge in this line of work has any right to be found therein. Any man who seeks the position of factory inspector simply because it pays a fair annual salary is little less than criminal in spirit; and any owner of a factory who, after being instructed as to what he ought to do to make his particular trade, buildings and premises as healthful as possible, fails to do so, is guilty of culpable negligence. It should be remembered that operatives form an important part, social and political, of the population of this great country. They are important citizens with all the rights which belong to men and women who live under the protection of the grand old ensign of this glorious republic. Let us, therefore, consider their preservation from disease and injury while contributing to the industrial pre-eminence of our Nation, honored in every clime under the sun, because of the security afforded its children, not only their inherited rights because of citizenship, but as endorsed by the law of God, and the generous spirit of a just and common humanity.

Dr. J. R. LEAL of Paterson, said the report virtually admitted that we are compelled to have sanitation by the labor organizations. If the law was enforced the factories would be perfect. If the inspectors did their duty, there would be nothing for this society to do. It would appear that the sanitary condition as a whole was better than that of the homes.

Dr. HENRY MITCHELL, Secretary of the State Board of Health, said the inspector has powers and can demand changes that he may deem proper. The local boards should attend to the execution of the laws.

Dr. JAMES A. EXTON of Arlington read the report on "Improvement of Sanitary Administration in Townships." The object of appointing the committee was to secure legislation. To this end they secured the introduction of a supplement to the Act to establish Boards of Health, asking for sanitary inspection, the appointment of a State Board of Examiners whose certificates should be an assurance of eligibility of the applicant to appointment as sanitary inspector. This was known as the Wildman Bill; it passed both houses of the legislature, but was vetoed by the Governor. All believed this to be a proper bill, and with the changes recommended by the Governor in his veto will be carried through the coming year, and hence the committee asked to be continued in order to push it. This was granted.

Mr. M. O. LEIGHTON of Montclair read a paper on

VICISSITUDES OF HEALTH INSPECTORS.

He said that trouble begins at once after the accession of the inspector to office, and multiplies. He is well abused. In the milk inspection he worked personally; supervised the analysis of the milk, the bacteriologic department and the inspection of the dairies. In cases of contagious disease he studied the source of infection, superintended the disposal of ashes and garbage, as also the plumbing. To these duties he added the examination of nuisances and a number of other matters. Complaints give a ludicrous series of pictures from noisy cows to vicious dogs, troublesome geese, leaky roofs and neighborhood quarrels. He is sure to make enemies unless he is extremely fortunate. A gentleman brings a bottle of water, shall we drink this? One must labor with him, pacify him; make him know that it is not necessarily baneful, even if it is muddy. He departs and talks learnedly of bacteria and albuminoid ammonia for a week. The next knows all about disease germs from the newspapers; boils his water and milk; suspects an epidemic in every dust cloud; diphtheria has broken out in his block, wants to know if it will be better to move away to his summer home till the case is well. Nothing but intelligent reasoning will do with him. He is shown the fact that there is no danger to his family, that the case is well isolated, can not extend, and to move may be a change for the worse. The next has no complaint nor quarrel with her neighbors, but wishes to inform the health board that so and so exists in such a place, but does not wish her name to be mentioned. Now, in nine out of ten such cases there is no cause for complaint. The next desires information as to the general health of the place, what contagious diseases exist. Such a visit is pleasant, and the inspector wants more of such. In the eyes of the citizen the health inspector occupies a peculiar position. The laws have invested him with powers so extensive and so useful that

it is well to know him. In order to be of service in the most efficient manner, he is confronted with many ideas as to what is best to do in each case. He must not believe in a weakened policy, nor advocate a two-faced principle. He must reach the same end by paths which conform to the idiosyncrasies of those with whom he has to deal. Tact, honest old-fashioned tact is needed, if the health officer wishes to obtain the best results. An old friend at the outset of the speaker's career said: "Remember one catches more flies with molasses than with vinegar." Again, he must fancy the feelings of those who believe their house is their castle and have him come in and tell that man his property is a nuisance. If he becomes offensive to the neighbors, a change must be made. Probably this man has had all this for twenty-five years, and all thrived with it, hence he is not willing to recognize any demand for a change. There is contagious disease in his family, his house is placarded, the family quarantined, and they can not mingle with the rest freely as formerly; all this provokes opposition, and needs the greatest care in its doing. All must be done in accordance with the most approved principles as to modern science, thus to produce the greatest amount of good, and must be carefully fitted to each case. In regard to the milk supply, he visits the dairy, inquires as to the cleaning of the cows, the stables, the hands of the milkers and the other hygienic needs, then as to the cooling of the milk, the cleansing of the bottles and multitudinous points. Think of the difficulties met with. This is nothing beside the problem of teaching the ordinary dairyman a few facts about biology of milk. He listens to the discussion of the bacterial action in souring milk, cooling quickly to stop the growth of the bacteria, cleanliness to prevent bacteria getting into the milk; a few call it bosh, or stare in open-mouthed wonder. One accepted all and fixed his place as required; one day he came in and said he should add a cream separator to his dairy, it was a bad plan to set pans of milk in the open air, lest a lot of bacteria should get in and do harm with their dirty feet. After the inspector had recovered he determined not to discuss the bacterial problem with a dairyman. The municipal government has trouble with the health officer. The police station is often offensive, the lavatories are unwashed for a long time; the garbage is not collected properly, even decently. In the report of the State Board of Health, you will find town after town show the same thing. You generally find swine feeding on offensive filth thrown out from a town, the garbage being disposed of just outside the town. These hogs are then brought to market as food for the citizens, and the inspector has to view this prospect and see his progressive people feeding on the unpurified product of their own garbage. It seems that the board of health stands idly by and sees the reeking offal of its municipality going to produce pork for human consumption. Thus it falls far short of the ideal for which it was created, and fails to be worthy of the principles by which it is governed.

Another point full of anxiety is his relations with his brother doctors. What is worse in any department of life than a careless inconsiderate person who is supposed to know the value of certain systems, and yet goes always as far as he dares in the wrong direction? I of course do not intend to include all doctors in this class, yet there are a few in each district. I have seen a doctor attend a patient in the desquamative stage of scarlet fever, and go to the bedside of a little sufferer weak and emaciated from fermental diarrhea. There will come a time when the general public will be sufficiently educated in public sanitation and the whole function of the board of health will be to keep in line those doctors who need to be looked after.

Finally, he mentioned the vicissitudes arising from his relations to women. To his mind this presents the widest variety of situations. It is the hardest kind of a problem, yet withal some of the most pleasant and profitable of that official's experiences. The "peculiar odor woman" sends a note desiring him to call at once. He puts off other and more important matters, hurries to the house when she tells him of a mysterious odor, and every one has the same tone and words. He spends hours in searching out the odor, she follows, rejoicing at every insanitary discovery. Should the sanitary condition happen to be perfect, no source of odor be found, he leaves that house having lost his reputation as an expert. In nearly every case, there is no cause apparent. Happily, few houses approximate the ideal, so he generally finds a few changes to recommend. So, he goes from disease to sewers, from sewers to milk, from milk to nuisances, till at the close of the day he leaves work unfinished and goes hoping he will be a long time dead.

In the discussion that followed, the speakers endorsed and enlarged upon the matters mentioned, and it was advocated that a plan be adopted, of adding a class to the colleges similar

to that at the Massachusetts Institute of Technology, from which Mr. Leighton graduated.

In the evening, the president, JAMES OWEN, C.E., delivered the Annual Address. His subject was

THE STATE OF NEW JERSEY AS A HEALTH RESORT.

In reviewing the conditions that make such a claim tenable, certain interesting facts and figures present themselves. To thoroughly appreciate the question, the axioms of the relation of man to his environments must be accepted and, in the effect of climate on humanity, it must be conceded that in certain regions of the earth's surface, human life is an impossibility save for limited period and confined to the individual; that in more favorable regions certain selected specimens can be developed but with little power of increase; that in still more favorable localities a large population can live, reproduce themselves, but of an adapted type; that with favorable environments men will increase faster than the capacity of such environment to furnish a living, the resultant is the tendency to migrate which is only restricted by physical obstacles or repressive customs; that the migration of the individual from the region to which he and his kind are especially adapted, as a rule acts detrimentally on his physique unless the climatic conditions of the new location are almost exactly similar to the original. This deterioration of the physique may not be developed in the individual but will in his progeny, till acclimatization perfectly ensues; that there is an inherent tendency in the physical organization of man to adapt itself to new conditions. It is a slow process, and may take three or four generations to arrive at a perfect organism. It must also be remembered that the so called salubrious climate does not develop the highest type of physical manhood; such type is generally achieved under harsh conditions. All these assertions are based upon the inherent physical tendencies and growth which are universal on every part of the earth's surface. In addition to that is the effect of mental effort on environments, and here a line of demarcation is found to physical development on climatic lines, which is hazy and indistinct, but that certain races make no attempt to improve their physical surroundings, and that other races are continuously bettering them by intellectual effort and actual manual work, is patent to all. The North American Indian from prehistoric time made no effort to change the physical condition of this country; yet within a century, the mental and corporal activity of the white race has practically changed the face of this whole continent and an appreciable portion of this activity has been on lines of what may be called sanitary improvement, showing that the effect of the intellect is to adapt the surroundings to man instead of man to his surroundings. This alternative gives the immense scope for sanitary work in all its ramifications; but one prominent factor must always be considered, and it is that the basis of all sanitary effort on the individual and his environments is the natural climate of the district in which he lives, and the climatic conditions must be distinguished as general or specific.

The general character of a climate in any locality is a natural condition that no particular effort of man can modify. Specific conditions can be changed by human effort, according to his mental acumen and physical energy. Adapting the foregoing principles to our State what do we find? 1. The aboriginal with a physical development adapted to the surroundings, with small power of increase and an utter inability to improve his conditions. This continued till within about 250 years, when the migration began and this has been kept up continuously. During that period, it has been proved that the general climatic condition of the State is positively favorable to both in the development of physique and in power of increase. As the earlier settlements were made on selected territory, the necessity for modifying specific climatic conditions was not apparent, but as population increased, the insalubrious localities were improved and changed till today a very small portion of the State can be considered uninhabitable from natural causes. The growth of the population of the State may be divided into three periods: That from the early settlement to the construction of steam railroads; this growth was mainly agricultural and with a very small urban population. From 1840 the growth of railroads stimulated the business activity of the State and then began the large increase of urban population till about 1865 the suburban or residential accretion began, and which now forms such an important section of the Commonwealth. It must be noted that the governing impulse of all migration up to 1865 was that of gaining a livelihood in the locality and in the State; since then, the motive has been largely for residential purposes and the paramount influence for a migration is the sanitary character of the locality. In 1737 the population was 47,369; 1840, 373,206; 1865, 773,700; 1895, 1,673,106. An analysis of this growth must be consid-

ered in the broad distinction as urban, suburban, rural, and, taking from the whole State the counties of Hudson, Bergen, Essex, Passaic, Mercer, Camden and Union, as those that are urban or suburban, the rest as rural, the division of the population on those lines would show: 1737, urban, 11,164; rural, 36,265; percentage of urban to rural, 23.4; 1840, urban, 125,563; rural, 247,743; per cent., 33.6; 1865, urban, 387,104; rural, 386,596; per cent., 50; 1895, urban, 1,109,768; rural, 563,438; per cent., 66. In the year 1737 the proportion is vague; on the other hand, in 1895, there are counties like Morris, Middlesex and Monmouth that have acquired a large urban and suburban population, so probably the percentage would be nearer the truth as 70, than 66 as above. Assuming this, it is desirable to ascertain what proportion of the population is, in using this State for residential purposes alone, with no business ties, governed solely in their selection of a home by convenience and sanitary surrounding and are generally known as the commuters. In this class we must collate all dependent upon the commuter and his family, located merely to supply his wants, and who leaves if he leaves. It is safe to say that every man who comes to New Jersey to settle in a suburban home with his family, has another who has come to supply his wants. There are many towns and villages in the northeastern part of the State, and also in the southwestern part, that have no other cause of existence than the suburban resident, and on the sanitary condition of these towns, cities, etc., depends their vitality and existence. In addition, there is the temporary accretion during the summer months, and this is due entirely to sanitary and climatic conditions, namely, those who crowd the seaside resorts and who are also scattered over the rural and mountainous section of the State. To determine accurately the proportion of the population that is purely residential in proportion to the whole number is a matter of difficulty, as intermingled with it in some places are industrial pursuits that make it difficult to segregate one from the other, and many of the cities, as Newark, Jersey City, Hoboken, Paterson, Camden, have a large number who do business in other places, but prefer this State as a residence, and their number is greater than is usually expected. Information gathered from the railroads as to the commuters is only partial. The Erie R. R. has 20,000 a day; the D. L. & W., 15,000. Passengers crossing the North River in 1886 were 58,894,000; in 1890, 72,260,000; in 1900 it is estimated at 100,000,000, of which 50,000,000 will be from Hoboken, Jersey City and Newark, 38,000,000 from other towns, and 12,000,000 from a distance of thirty miles. Assuming at present 90,000,000 a year, deduct for Sundays, etc., would give a daily average of 128,000 to and from. Allow half as regular commuters and we have 65,000. Taking the basis of commuters on the D. L. & W. to population, the proportion of immediate dependent inhabitants to commuters as 6 to 1, we have a population in northern New Jersey of 400,000 as purely resident; in addition, 50,000 more can be counted in the southern part adjacent to Philadelphia. Assuming, as approximately correct, 250,000 the visiting population in the summer, we have 700,000 people who have no stronger tie than sanitary condition and therefore the greater *onus* on the varying State and local authorities to preserve the good reputation for climatic and topographic excellencies. Curiously enough, the State has been a byword in the country at large for bad climate and unsatisfactory conditions. Malaria and mosquitoes have been synonymous with New Jersey, and to have lived such a reputation down, and to be the State *par excellence* for location on pure sanitary lines, show that mental effort has been joined with natural conditions to achieve such a result, and that brings us to the culminating axiom of sanitary laws, that the tendency of congestive humanity is to destroy itself, unless intelligence and energy are combined to offset such disasters. This combination of intelligence with energy is classified as sanitation. In no State in the Union is this more strictly demanded than with us, and to have proper sanitation, intelligent supervision is demanded and a conscientious obedience to such a supervision by the committee at large is absolutely essential. No more intelligent understanding of the sanitary condition of any locality can be arrived at than by studying the death rate, and I have worked out the rate for the different towns, etc., for the last five years. A synopsis will probably be interesting. A criticism may be raised that five years is too short for a proper conception of death rate, but two facts may be submitted: In the last five years the returns have been more accurate, and the death rate is decreasing so rapidly, that averages for ten years would give a wrong impression.

He gave the rate for nine agricultural counties as 14.6 per thousand of population; of eight suburban counties as 17.8; of seven urban counties as 20.1; of four seaside counties as 16.3; the death rate in the seaside counties conveys a false

impression, as all the deaths are given, including non-residents, while the ratio is on the actual population. Sussex, in the mountains, has the lowest, as might be expected. Salem next, is on the borders of the river with no high land but a loamy sandy soil. Hudson is the highest, due to a congested population and lack of sanitation. Curiously, the rate of the suburban sections is not much greater than the rural rate. Ten years ago it was much higher. The improved rate is due to better conditions. The suburban sections with cities eliminated show the effect of specific conditions and how important to neutralize congestion by care and watchfulness. Essex county is 21.2; without the city of Newark, it is 15. In basing an estimate of the sanitary condition it is proper to assume an ideal rate and criticize any departure, so we find three towns in Hunterdon County with a rate of 10; so with several other counties. Yet it would not be safe to assume 10 as the ideal, for in most counties with low rates the population is decreasing and children are few. Hence complete sanitation and proper climatic conditions will concede a rate of 13, and that is about the average of the purely rural section where there is no congestion, pure air and water are available with little care and with the practice of the ordinary ideas of cleanliness.

In the urban and suburban sections different conditions prevail, and here sanitation comes into play. Proper drainage, pure water, complete sewerage, removal of garbage and of ground water are essentials of a low rate, and in Essex County we find East Orange with a population 18,000, death rate of 12; Montclair 14; Bloomfield 13.6; West Orange and South Orange, pure water, no sewerage 13.5 and 12.9. This rate of 13 can be achieved and should be the desideratum, and all in authority in the State should examine their locality and find the cause, if more than that. The science of sanitation is now crystallized into a practical profession. In all works of this character there are two factors, the individual and the community; thus if a town puts in a system of sewerage and the individual adjusts his property to it they are in accord. These factors have both to be educated but in different lines. Sometimes the individual is willing and the community not; and *vice versa*. We need here education and legislation, and I think the State has done its duty in that line. The State Board of Health, under its former secretary, Dr. Ezra M. Hunt, and its present efficient one, Dr. Henry Mitchell, laid down lines of procedure in sanitation for this State, first to educate the people to the necessities for more care for their health, and then to pass laws to enable them to take that care. Probably with the exception of the State of Massachusetts our State has the most complete sanitary legislation extant, and its full adoption would bring the death rate well toward the ideal of 13, and only the neglect of individuals and communities allow it to stand at 20 and 23 as it does some places. Provision is made for health boards of all kinds. Every municipality has power to get good water and sewerage, collect garbage, regulate plumbing and insure undulterated food. Forty-eight towns and cities have systems of sewerage accommodating a population of over 1,200,000; probably the dwellings of 750,000 are sewerred, fifty have water-works supplying good water. In many places drainage systems are perfect, and in all the large cities supervision is exercised over the house construction and plumbing. The effect of this Association is not confined to this room, hence my detailing these matters at the risk of being tedious. Twenty-five years ago I had the privilege of being associated with Dr. Sanford B. Hunt, the father of the Commissioner of Passaic Valley Sewerage, who is with us tonight, in sending out notices for the first meeting of this Association held in Newark. The meeting was large and enthusiastic and thence originated all the sanitary work of the State. Then the State Board was organized and both organizations have forwarded the great work; coupled with this is the great progress in medical science, and as an engineer I am not able to outline the details of this growth; yet I will allude to the desideratum in sanitation, that the doctor and the engineer should travel in the path of progress hand in hand, one to exercise his power to prevent disease the other to eliminate it.

DISPOSAL OF GARBAGE.

Mr. RUDOLPH HERRING, C. E., of New York, then spoke upon the "Disposal of Garbage." In Europe cremation is generally the plan by which to get rid of the garbage. In this country we have a variety of ways. Garbage is kitchen slop, ashes, dust of the streets, in fact all refuse save that in the cesspools. In some places cremation gives good results. Some report this plan as more valuable and less expensive. Some separate the slops from the rest and feed it to animals. The special objection is that it is apt to ferment and become most offensive and also prove injurious to the animals. Economy is demanded in

the disposal of the garbage. Cremation is objected to because it generally proves a nuisance by the odor given forth in the process. Hamburg uses cremation and finds it very satisfactory. They show that it need not be conducted so as to be a nuisance. The products are regarded as an excellent fertilizer. At present the question is as to the cost before any plan is adopted. Usually the cheapest plan is adopted. Boston is now about to adopt cremation. In case of an epidemic cremation is the safest plan. Brooklyn and New York now use the reduction plan. This disposes of the refuse of the house only, while cremation must follow for the rest. Too often these matters are decided by political influence, not according to what is proper or best. In conclusion he said cremation is always the best for sanitary purposes and from an economic point of view.

Mr. M. N. BAKER, C. E., of the Upper Montclair, agreed most heartily with all the speaker had said, unless it might be that one or two points of minor importance were open to discussion. In his own household he had found no difficulty in disposing of all the garbage by burning it in the kitchen range. This he considered preferable to having an odorous receptacle standing about. The plan is not practical, however, unless given personal attention by some one other than the ordinary servant. It never will become the universal method of disposing of garbage. Plants for the disposal of garbage have proved failures, which is largely due to the fact that the garbage-disposal problem is not approached by most citizens in a scientific manner. If a sewage or water purification plant is to be built, an engineer of good standing is called in to aid in the undertaking. But when a city finds it necessary to make some change in its method of garbage disposal, instead of employing an engineer to outline a plan best suited to the needs of a city, a committee of the city council sets forth on a visiting trip to garbage plants and is very likely to come back most impressed with that system of disposal the commercial agent of which talked the smoothest or made the best impression by whatever means. The questions involved in garbage disposal are scientific ones and should be studied in a scientific manner. If cremation is to be employed it is a question of how many heat units will be required and how they can be generated and applied to the best advantage. If a reduction process is to be installed, machinery will be needed to secure the grease and fertilizing material. In either process the questions arising are best answered by the engineer rather than the layman; in fact the layman can not answer them. One reason for the high prices for garbage disposal prevailing in most cities where the work is done by private parties is the short term of the contract. Contractors are forced to provide expensive plants and are then limited to one-year contracts. They know the job may go to some one else at the end of the period, and hence must bid enough to cover the risk. The lesson from this is either to make the contract longer or have the work done by the municipality. In the collection of garbage he said, experience shows that but a small proportion of the population is served when the work is entrusted to private scavengers instead of having a general public service, either by the city or by contractors paid by the city.

(To be continued.)

SELECTIONS.

Perforation of a Gastric Ulcer into the Pericardium. Mr. Collingwood Fenwick has reported in the London *Lancet* for August 14 a case of the above rare accident, as follows: On July 30 I was summoned to attend a man who had been taken suddenly ill. Arriving at his house three minutes after receiving the summons, I found him lying dead on a garden chair. The history I obtained from the widow was as follows: Her husband's age was 55 years, and until recent years he had been a builder. On the day of his decease he returned home from a walk, but made no complaint and appeared to be in his usual health. He had never complained of pain after food, or suffered from vomiting or any other symptom of gastric disease. Immediately on finishing his meal, which consisted of tea, fish, and bread and butter, he rose from the table complaining of pain and palpitation. After walking a few yards he sat down, and his wife, noticing that he looked very pale, administered some whisky and water, but he expired in about a minute.

Necropsy. The results of the postmortem examination, made twelve hours after death, were as follows: The body was that of a stout elderly man. The lungs were emphysema-

tous, the right lung being bound to the chest wall by strong pleuritic adhesions. The pericardium was found to contain several ounces of tea, which smelled of whisky, and some particles of fish. On the lower surface of the pericardium a small aperture was discovered, admitting a stout probe, which was passed downward through the diaphragm into the abdominal cavity. The heart itself weighed thirteen ounces and was extensively infiltrated with fat; the valves were normal. The anterior surface of the stomach was found to be firmly adherent to the under surface of the diaphragm, and on opening the viscus a chronic ulcer the size of a shilling, with indurated edges, was seen to be situated about the center of the lesser curvature. From the base of the ulcer a sinuous track led upward, and to the right, through the substance of the pericardium. The stomach contained fourteen ounces of undigested material, composed of tea, fish and sodden bread. All the other organs were apparently healthy.

In a later issue of the *Lancet*, an editorial writer offers the following instructive comments upon the case. The probability of a gastric ulcer perforating the wall of the stomach depends chiefly on its situation. An ulcer on the anterior surface of the stomach will almost certainly lead to perforation if the ulcerative process continues; but should the ulcer be situated on the posterior wall adhesions form very readily, so that the stomach becomes adherent to the diaphragm or to the left lobe of the liver, but the diaphragm itself may become perforated by an extension of the ulceration, and then the ulcer may open in the left pleural cavity or into the pericardium. Perforation of the diaphragm by gastric ulcer is decidedly a rare occurrence, and even when it does occur the pleura is much more frequently affected than the pericardium. Of twenty-eight cases of perforation of the diaphragm by gastric ulcers, collected by Ludwig Pick, only ten were cases in which the ulceration had perforated the pericardium. In an earlier issue is recorded a very interesting case which occurred in the practice of Mr. Fenwick, in which a gastric ulcer had perforated the pericardium with an immediately fatal result, and yet no previous symptoms had occurred to point to the presence of the gastric ulcer. In four of the ten cases collected by Pick the two surfaces of the pericardium had become adherent before the ulceration had perforated, so that the ulcerative process involved the substance of the heart itself.

The Period at Which Old Age Begins.—Dr. Leake, in the *Medical Examiner*, argues that age sets in indefinitely when the forces of life begin to flag. Some men are twenty years younger physically and mentally than other men of the same age. It is self-evident then, that old age does not begin at any set time, so far as the divisions of time divide the periods of life, but that it has to do with that subtle agent known as the vital force, an acquaintance with which enables the analytical mind to become proficient in prognosis by weighing in the balance the vitality on the one side with the pathology on the other. Insurance companies say that a man over 60 years of age is not incurable. The truth is, many men under that age are insured and prove less profitable risks than many men would be over that age for reasons stated above. A more equable and profitable rule could be adopted if the companies could receive conscientious and competent work from the medical examiners, which an extensive observation prompts us to say is not done as a rule.

The indications of old age may be noticed by ocular inspection. The weight of years is manifested by the stoop figure, the walk is less elastic, the rounded figure gives place to the spare habit of body, the wrinkle of time mounts the cheek, while the frost of many winters mantles the brow. The typical healthy person who attains to old age is spare of body, and old age emphasizes this fact by causing a paucity of adipose tissue. So the wrinkle of time after all is kindly in its nature. Physiologically we notice that a diminution of the physical

energy is accompanied by a corresponding diminution of the power to eliminate waste material from the body. Elasticity and strength give place to hardness and brittleness of nearly all of the tissues of the body. The general health may be good, because there is a harmonious balance between the action of the nervous system and the circulatory system. However, the former is less responsive to external stimulation, and the latter is less vigorous in old age. The vital processes conducted by the circulation, respiration and metabolic changes in the tissues are less active. There is diminished adaptability of the whole system to changes in the environment, and less ability to meet the requirements of emergencies, such as sudden demands of muscular and mental strain.

The senile conditions and diseases that render old age uninsurable are numerous and obvious. In the first place, weakened digestion and assimilation; the weakened vigor of the circulation and glandular system necessarily weakens the power of eliminating the excrementitious substances, which gives rise to pernicious nutrition, and that in turn is the cause of the tendency to develop malignant or benign growths in different parts of the body in old age. The strong tendency to over-eat and under-drink, together with the natural decline of functional power, gives rise to a condition of lithemia, which is the prime cause of the majority of deaths in old age. In the healthy state that great glandular furnace and chemical laboratory, the liver, is capable of transforming an excess of nitrogenous matter, which may result from metabolism of tissue or exist in the food consumed, into the highly soluble excrementitious substance known as urea. This excrement is eliminated from the blood mainly by the kidneys and to a much less extent by the skin. Now in old age, with the functional power and natural vitality on the wane, together with the strong tendency to over-tax this function of the liver, we find this waste is not converted into urea, but into uric or lithic acid, a comparatively insoluble excrementitious and toxic substance, which if it appear in the blood in sufficient quantity, and is long enough continued in circulation through the urinary tubules, sets up irritation and inflammation, which inevitably impairs the function of the renal epithelium, and we find this poisonous substance is not eliminated from the system, but accumulates in the blood. This explains why old people are almost universally troubled with disease of the liver, kidneys, bladder and prostate gland. The unstable circulation, atheromatous changes and brittleness of the walls of the blood vessels, with the tendency to over-tax the digestive apparatus, is the cause of many old people going to "that bourne from which no traveler returns," by the apoplectic route. Hereditary diseases naturally manifest themselves when the vitality is upon a low plane, when the general health is below a certain level; so we are not surprised to find certain dyscrasic and latent tendencies manifesting themselves at this period of life, when the natural vitality is waning. The diseases most frequently found to be the cause of dissolution among the aged are pneumonia, diseases of the liver and urinary organs, consumption, cancer, apoplexy, gangrene.

Old age is not insurable, because the expectancy of continued life is too uncertain. The question of time obviously enters largely into the fact that makes a risk profitable or unprofitable to the company writing the contract. Experience has taught that mankind over 60 years of age are not profitable risks, because the life tenure is too short. The agencies of dress reform, physical culture and self-knowledge, which are beginning to unfold themselves by an educational process at the present time, will tend to increase the longevity of the human race. The writer expects that two generations hence the time limit can safely be extended to seventy years. The enemy to longevity is self-indulgence. People who have reached an advanced age may prolong their lives and greatly add to the comfort of their declining years by diminishing the quantity of food ingested; by taking food more frequently and in smaller amounts; by taking only easily digested food; thereby avoiding too large a residue of waste matter, either in the intestinal canal, or in the form of excrementitious matter in the blood.

PRACTICAL NOTES.

Sodium Salicylate and Caffein in Uterine Atony.—Katzenellenbogen states that he has found this combination effective in securing energetic contractions of the uterus intra partum. Twenty to thirty centigrams were injected subcutaneously.—*Semaine Méd.*, December 29.

Electric Apparatus for Migraine.—At the meeting of the Berlin Medical Association, December 8, L. Ewer exhibited an apparatus consisting of an accumulator and dynamo with a rubber knob attached, which imparts slight impulses as it rotates, which, he states, cure in a few minutes all cases of migraine, except the angioparalytic form.—*Deu. M. Woch.*, December 23.

Bremer's Macroscopic Test of Diabetic Blood.—Object glasses are smeared with normal and the suspected blood and placed ten minutes in the oven at a temperature of 135 degrees C. A 1 per cent. aqueous solution of Congo red or methylene blue, stains the normal blood the corresponding tint, while the diabetic blood is only slightly or not at all affected by it. The stain should be applied from one and one-half to two minutes; if left longer the difference becomes less marked.—*Deu. Med. Woch.*, January 6.

Serum Treatment of Ozena.—At the Italian Congress of Otorhino-laryngology held at Rome in October, Della Vedova and Belfanti proclaimed the efficacy of serotherapy in ozena, which they have established by much experimental work. Masini also conceded its value, but considers cataphoresis with slow electrolysis the chief reliance. Others recognized the benefits to be derived from serotherapy in certain cases. . . . *Wratsch* No. 40, reports another case of the complete recovery of a child of 5 years after a single injection of 10 cm. of Roux's antidiphtheria serum.

Therapeutics of Whooping Cough.—According to Busdraghi's experience a treatment that disinfects, soothes the nervous system and keeps up the strength is much better than any of the so called specifics. For the first he advises spraying for ten minutes a day with a 2 per cent. solution of carbolic. For the second he prefers trional, which ensures a calm, lasting and strengthening sleep, 0.1 to 0.5 gram according to age. He adds a teaspoon of a 1 per cent. solution of chloral in very obstinate cases. To keep up the strength he gives one-fourth to one-half teaspoon somatose in milk three or four times a day.—*Klin. Therap. Woch.*, January 9.

Atropia in Delirium Tremens.—The remedies employed in delirium tremens are only relatively effective, but cold baths affect the syndrome favorably. Reasoning from the assumption that they stimulate the inhibited cerebral centers. Tuwim of St. Petersburg, has been trying atropin, which also stimulates the centers, and announces that it is extremely successful. In ten out of eleven cases a single injection of one milligram of atropin threw the patient into a calm and deep sleep in fifteen to twenty minutes. In the one case in which delirium persisted it was complicated with erysipelas, and yielded finally to a cold bath. He recommends, therefore, subcutaneous injections of atropin, supplemented if necessary by cold baths in the treatment of delirium tremens.—*Semaine Méd.*, December 29.

Ambulant Treatment of Fractures of the Limbs.—Lambret of Lille recently osteotomized the femur of a patient for a genu valgum. The next day the patient walked with crutches, the day after with a cane, and "after that with his hands in his pockets." The apparatus used has a plaster cast around the pelvis in which is mounted a sheet metal crescent, which rests on the ischium. A piece of sheet metal also encircles the knee, below which is the stirrup. The entire apparatus weighs four kilos. The patient walks with the pelvis, the knee rectilinear. He urges the more general adoption of the ambulant treatment.—*Nord. Méd.*, January 1.

Length of Time a Lying Patient Should Remain in Bed.—An extensive series of tests at the Breslau Clinic, is reported by Brutzer in the *Zf. f. Geb. u. Gyn.* (Vol. 37, No. 3), which establishes the fact that in certain cases discriminated by the physician, the patient can leave her bed on the second or third day, and that it is injurious rather than beneficial for normal women to stay in bed more than five days at most. Danger of lacerations

is much more imminent from defecation or urination than simple moving around. Embolisms do not occur after the second day in normal women if we accept the published statistics. The patients who had quitted their bed early were much stronger when finally dismissed at the tenth day, than those who had kept the reclining position longer.—*D. M. Woch.* January 6.

The Value of Euquinin as a Tasteless Substitute for Quinin mentioned in the *JOURNAL* (January 1, page 38), is confirmed by the experience of the Milan hospitals where it has been tested on a large scale. Pangrossi also reports fourteen cases treated with it. The conclusions are as announced, that euquinin possesses the same specific and general properties as quinin, in the same intensity, and should be administered in the same doses. The disturbances caused by quinin intoxication do not accompany the use of euquinin, and it has also been found a stimulant to the appetite. A bitter taste develops if held a long while in the mouth, which justifies the assumption that in the stomach it has the tonic property of a bitter substance.—*Gazz. degli Osp. e delle Clin.*, No. 136, 1897.

Treatment of Chronic Cervical Gonorrhea.—F. Lehmann reports several tedious chronic cases cured in three weeks. After cleansing the parts with a soda solution, he introduced into the cervix a conic metal dilator fitted into a small metal tube speculum, the whole introduced through a vaginal speculum. The dilator is withdrawn in the course of five to ten minutes, and through the small tube speculum a tampon dipped in the desired caustic is applied to the entire surface of the cervical mucosa, as it is exposed by the gradual withdrawal of the small speculum. He prefers 5 per cent. argentic nitricum, but chlorid of zinc or argonin can be used. The best results were attained with nulliparæ. Where there is much infiltration, the massage by the dilator is an important factor.—*Deutsche Med. Woch.*, January 6.

Sulpho ricinate of Phenol in Tuberculous Laryngitis and Rhinitis.—Ruault's solution of pure phenic acid in acid sulfo-ricinum has been recently used by Magenau in forty-five cases of tuberculous laryngitis with such benefit that he recommends it to others. In nearly every case the sputa became more fluid, expectoration easier, the voice clearer, swallowing less painful. None were cured completely, but in twenty-seven cases followed to date, twelve were remarkably improved; nine slightly and six not at all. It was applied locally in a 20 to 30 per cent. solution two or three times a week, preceded by cocaine in some cases. Two cases of tuberculous rhinitis were also much improved, and nearly all cases of "dry" and simple and pachydermic laryngitis.—*Munch. Med. Woch.*, 1897, No. 37.

Value of Electricity in Sciatica.—In a communication to the *Deutsche Med. Woch.* of January 6, Stanowski protests against Möbius's recent assertion that ischias is not benefited by electrotherapy, and describes several extremely severe cases of long standing cured completely by it. He states that he has secured the best results with: 1. The application of the galvanic current, avoiding much variation in the strength of the current; 2, the application of an electrode large enough to cover the entire region from the sacrum to the great trochanter on the affected side (30x20 cm.); 3, applying the other electrode to the sole of the foot, to which it must correspond in size; 4, the current passing down the leg, the positive pole on the sacral region and the negative pole on the foot; 5, half hour treatments at least, and better still, three quarters to an hour each time; 6, the current so graduated that the patient feels no unpleasant sensation from it, especially no tendency to cramps in the leg. He commences with 30 milliamperes in the first sittings, afterward 8 to 10. The electrodes must fit close to the surface, which is protected by a sponge on the sole and four folded towels on the sacral region. The plates are held in place with a leather band. In three and one half months he transforms helpless, pain-racked invalids into vigorous bicycle riders; his success has been constant.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, FEBRUARY 19, 1898.

THE MOBILE CONVENTION.

The most important sanitary Convention of recent years was held in Mobile on the 9th, 10th and 11th of February. The Convention was composed principally of representatives from the Gulf and South-Atlantic States, a few invited members being present. The Committee on Resolutions were divided ten to two, ten favoring the Spooner Bill as it stands, and two favoring the modified Caffery Bill. These two were from Georgia.

On these reports reaching the Convention they were debated at length; the Hon. W. H. CLARKE of Mobile made a substitute resolution, and the following action was taken (we quote from the minutes of the meeting):

Mr. CLARKE asked leave to withdraw his substitute and offer another in its place. Granted.

Col. KAY, of the minority report, withdrew the report.

Dr. HORLBECK withdrew the majority report and moved that CLARKE'S substitute be adopted. Carried unanimously and amid great applause. The substitute reads as follows:

Resolved, That it is the sense of this Convention:

1. That Congress be requested to provide for a department of public health as soon as practicable.

2. That it is the sense of this Convention that Congress should enact laws to provide for an efficient maritime quarantine to be uniform and impartial in its application to the different commercial ports of this country, so as to give to no one or more of them undue commercial advantage over the others, and to be enforced by the several State and municipal quarantine or health boards, if they will undertake so to do, leaving also to the States the power to prescribe and enforce additional reasonable safeguards of the health of their communities, provided that such State action shall not unreasonably obstruct commerce.

3. That Congress should aid the several States in establishing and maintaining uniform, reasonable and efficient quarantine laws for affecting but not regulating interstate commerce, leaving to each State adequate power to protect as it shall deem best the lives and health of its people.

4. That Congress should leave exclusively to the States the

regulation of their purely internal commerce and the providing of such quarantine and sanitary law regulations as they may deem advisable to that end.

5. That in the framing of quarantine laws and regulations, and in their enforcement, Congress should avail itself of the learning, experience and ability of the medical profession in the fullest measure possible, and especially by way of an advisory council.

It will be seen that the essential features of the bill recommended by the Committee of the AMERICAN MEDICAL ASSOCIATION and the American Public Health Association are thus endorsed by a great convention vitally interested in this question, recommending first the establishment of a department of public health, and that quarantine regulations be adopted with the aid and advice of a sanitary council. The pretensions of one man representing a single bureau were thus overturned. We shall give this week and next a full text of the proceedings of this convention.

It now remains for each member of the ASSOCIATION to immediately write his member of Congress and Senators, urging the passage of the bill on the lines of the Spooner Bill, establishing a commission of public health, with an advisory council.

The Convention was orderly and harmonious throughout, and while the discussions were earnest and carried on by men who felt deeply the responsibilities devolving upon them and upon the convention, were never characterized by anything but courtesy and kindly feeling.

The opinions of eminent lawyers of the South in regard to constitutional questions, seem to be conclusive with regard to the enforcement of municipal health regulations by acts of Congress, that those favoring such action by Congress will have to suggest a constitutional amendment to be passed upon by the several States in their legislatures, before such action can be taken, and even then it is doubtful if there is any widespread demand for it at this time.

The State of Mississippi last week made an appropriation of \$50,000 to be placed at the disposal of its State Board of Health (which had been previously almost without funds, and hence was crippled during the last epidemic). The legislature also provided that the regulations of the State Board should be supreme throughout the municipalities in the State, and that whenever attempted to be overrun, the governor was authorized to call out the militia to sustain the board. This is a long step in advance and will probably solve the problem so far as interstate commerce and interference with common carriers is concerned. It will also have a very healthy effect in preventing a panic, which is more disastrous in most cases to commercial interests than the epidemic itself. It will be recalled that at this time the National Government is engaged in running a quarantine camp, and vaccinating citizens of Alabama at an estimated expense of three or four hundred dollars a day.

It is understood that the House Committee on

Interstate Commerce (of which Mr. HEPBURN of Iowa is chairman) have resolved to have hearings this week. By the time this reaches our readers the hearings will have been concluded. It is to be hoped that the members will see the importance, if they wish a department or a commission of public health, of moving in this matter instantly and without delay.

Let us have a commission of public health with an advisory council!

THE CAUSE OF DEATH FROM ELECTRIC SHOCK.

The constantly widening employment of electricity, the common use of powerful currents under conditions and in places where some slight derangement may give rise to serious accidents, and the too frequent occurrence of these, make the subject of their cause and manner of occurrence one of unusual interest. It is not necessary to speak of the dangers from fire, which are perhaps really the most serious ones we have to guard against, as the ones most likely to be encountered; the less frequent, but still sufficiently common, perils to human life directly from the current fall more properly into the scope of medical investigation. It is an important question just how death occurs from a powerful electric shock, whether it is instantaneous or not and just what organs and centers are particularly involved. By knowing this we can best estimate the value of any therapeutic resources in these cases and act intelligently in the presence of these accidents.

It has been the opinion of some physiologists that the postmortem findings have indicated that death occurred in these cases from arrest of the respiration, while others have conjectured that cardiac arrest was rather the cause. To settle this question as far as possible, two English physiologists, Drs. THOMAS OLIVER and ROBERT A. BOLAM, undertook a series of experimental investigations, the results of which they have published in the *British Medical Journal* of January 15. These experiments utilized dogs and rabbits, which were subjected, under ether, to high potential currents, the blood pressure and the respiration being instrumentally recorded the while. The alternating current, usually considered the most deadly, was alone employed.

The results of these experiments seem to support the view that death from electric currents of high potential is chiefly, if not solely, due to cardiac arrest. The experimenters found that when a sufficient current was used, the dogs or rabbits succumbed instantaneously with stoppage of the heart; if one of somewhat less potential is employed there may be suspended respiration with the pulse first quickened and then arrested. Usually the heart was first arrested, while rhythmic respiration continued for some appreciable time. Only with very high currents were both arrested together simultaneously. In no case did

they observe primary permanent arrest of respiration with continuance of the heart's action. The indications of the recording instruments were supported by those from direct auscultation. After death the left ventricle was found in some of the animals nearly empty, while the right ventricle and large veins were distended with dark fluid blood.

So far as these experiments go the evidence of death by cardiac arrest was conclusive. They did not, however, give any absolute data as to the relation between the strength of the current and the fatal effect; the voltage was not necessarily in proportion to the size of the animal. It appeared possible that younger and less highly organized animals required stronger currents for the fully lethal effect than older and more highly organized ones, but this is stated merely as a suggestion. It is a practically well known fact that it takes more voltage apparently to kill a man than it does some larger animals, which is in part, if not altogether, in accordance with the above statement. It would be a very fortunate thing if we could obtain sufficient data as to every fatal or non-fatal accident from electricity as it occurs from competent observers on the spot, but the conditions are seldom such as to permit this, therefore generalizations as to the exact behavior of the human organism under all the varying circumstances are hardly possible. Much, however, might be learned by careful investigation of each case, and OLIVER and BOLAM quote the testimony of workmen who have observed victims of electric shock make a few respirations after its reception. The currents and methods used in the legal electrocutions in New York are not such as to be altogether comparable to most of the accidents that occur, and of course they do not allow the graphic records of blood pressure and respiration that can be secured in physiologic experimentation. The investigations of the English authors have therefore a special value, as bearing upon the sometimes questioned efficiency of that method of capital punishment. There can be little doubt but that death must be instantaneous in the electric chair, and the continued application of the current would certainly insure it were there any question of the possibility of resuscitation.

As regards the methods to be used for restoration of the victims of electric shock, OLIVER and BOLAM think artificial respiration is after all the most hopeful one, notwithstanding the fact that cardiac arrest is to be considered the chief feature in causing death. It would appear that restoration of the respiration was the best cardiac tonic; many others were tried as well as direct cardiac stimulation and relief of the loaded cavities, but generally if not universally without effect. By artificial respiration they succeeded twice in reviving animals, once after twenty minutes efforts, but they consider this, or at least half an hour, as

about the limit of time in which there can be any hope from its employment.

As regards the question of the relative deadliness of the continuous and the alternating currents, there is evidently in their minds some room for difference of opinion, and they propose to give the results of their investigations on this point in a future communication. D'ARSONVAL, as is well known, has maintained that the continuous current is the more dangerous owing to its greater chemical action, and it may be that there is reason in this opinion. His other claim, that death from simple electric shock is more apparent than genuine, would seem to be overthrown by the experiments of the British investigators. If it is only very exceptionally that resuscitation can be effected in the dog, there is no reason why with stronger currents the same is not true with the human species. The conditions of experiments by skilled physiologists are much more satisfactory than those of the occasional accidents and the conclusions derived from them much more convincing. In the reported cases where a current of several thousand volts has been passed through the human organism without causing death, there are too many unnoted possibilities to make the conditions comparable to those of careful physiologic experimentation by skilled observers. We do not know the minimum limit of voltage required to kill a man under all circumstances, but there can be little question, none the less, of the dangers of high potential electric currents.

DISEASES ASSOCIATED WITH PERSISTENCE AND ENLARGEMENT OF THE THYMUS GLAND AND GENERAL LYMPHATIC HYPERPLASIA.

In the recent Bulletin of the Ohio Hospital for Epileptics, at Gallipolis, Ohio, Dr. A. P. OHLMACHER, the Director of the Pathological Laboratory, describes postmortem examinations in certain cases of epilepsy. In three of the five cases examined there was found a persistent, enlarged thymus, and in four of the cases there was a more or less general lymphadenoid hyperplasia. On this account he calls attention to the other conditions that frequently occur in connection with thymic enlargements, namely: 1, so-called thymic asthma; 2, sudden death in adults with persistent thymus; and 3, exophthalmic goiter.

Thymic asthma is the laryngismus stridulus of the English and American clinicians. Its anatomic basis has given rise to much discussion in German literature; the strife has concerned especially the relationship of the enlarged thymus usually present to the affection, and the controversy is still unended. Thymic asthma or laryngismus stridulus is usually a benign affection, and yet very many cases of sudden death in infants are ascribed to this disease. The paroxysm of laryngismus stridulus ending in sudden death does not require any description at this time. Suffice it to

say, that some children in apparently full health have expired suddenly, in the presence of witnesses or in the arms of parents; others have been found dead in bed, and in at least one case criminal proceedings were brought against the nurse on suspicion of foul play. At other times infants have been found dead in bed beside the mother, and it has been thought that death was caused by mechanical suffocation, until the autopsy brought out the gross pathologic findings about to be referred to. Undoubtedly very many of the death certificates in which children are said to have died from convulsions include cases of thymic asthma.

KOPP¹ gave the name of thymic asthma to laryngismus stridulus on account of the enlargement of the thymus gland so often observed. The majority of the writers who have studied the anatomic changes in thymic asthma have noted the enlargement of the thymus, and while all do not agree as to its causal bearing yet the trend of opinion is to look upon it as the most important factor. In addition to the enlarged thymus the evidences of rickets are often observed in the bones. GRAWITZ² was the one to lay the greatest stress upon the importance of enlarged thymus in these cases.

In his second case, which concerns a six-month baby who died suddenly in its father's arms, GRAWITZ found a hyperplastic thymus, rickety changes in the ribs, enlarged intestinal follicles, enlarged spleen and enlarged mesenteric glands.

PALTAUF³ made an extended study of the other lymphatic changes in thymic asthma, and he found that many of the infants dying from this affection presented a pale skin, well developed fat layer, enlarged spleen, and the epiphyseal changes of rickets, with enlarged lymphatic glands in various parts of the body. Now, these accessory changes which are usually present may be looked upon as indicating that thymic asthma is in some way related to some constitutional disorder, to rickets, or to the so-called "lymphatic constitution." The question as to the exact causation of the clinical symptoms of laryngismus stridulus still remains open. The pressure theory is hardly sufficient to explain all the cases of sudden death, and yet there can hardly be any doubt that hyperplasia of the thymus may cause dangerous and fatal dyspnea by producing tracheo- or broncho-stenosis, because SIEGEL⁴ has reported the recovery of such a case in a 2½ year-old child after placing the enlarged thymus outside the chest cavity. The question has, however, assumed a broader form, since it has been pointed out that the thymic enlargement is only a part of the general hyperplastic condition of the lymphadenoid tissues of the body.

¹ Ohlmacher, loc. cit.

² Deutsch. Med. Wochenschr., 1888.

³ Wien. kl. Wochenschr., ii. iii.

⁴ Centralbl. für innere medicin, 1896.

Sudden death in adults with persistent thymus has also been described in German literature. Most of the cases have occurred in young and apparently healthy adults, the victim suddenly falling dead. The unexpected death often takes place under conditions that give it a not only marked pathologic but also medico-legal interest. The persons may be found dead, they may die suddenly in the presence of spectators, while bathing, by falling into the water and drowning, during surgical narcosis and surgical operations. Cases coming under these various categories have been described by NORDMANN,⁵ VON RECKLINGHAUSEN,⁶ PALTAUF and others. Now, in these cases there has been found, first, a real enlargement or a persistent thymus, and secondly, hyperplasia of the lymphadenoid tissue in various parts of the body. The general tendency is to look to the whole picture of lymphatic hyperplasia for an explanation of the disease, rather than to confine the attention solely to the thymus.

It seems that after exhausting all possibilities, as cardiac muscular or ganglionic affections, capillary bronchitis, etc., a number of cases of sudden infantile death, with the symptoms of thymic asthma, and of sudden death in adults, both showing hyperplasia as well as persistence of the thymus and general lymphadenoid hyperplasia remain, which can not be explained on any other grounds than by assuming some connection between the changes in the lymphatic tissues and the fatal ending.

VON RECKLINGHAUSEN⁷ also calls attention to the fact that the arteries are usually narrowed in the "lymphatic constitution."

The thymus gland is frequently persistent and enlarged in exophthalmic goiter. The frequency of persistent thymus in this disease is entirely too great to be accounted for on the score of accidental coincidence. This has been emphasized by HEKTOEN⁸ in an article on hyperplastic persistent thymus in exophthalmic goiter. HALE WHITE⁹ and others have shown that in some of these cases there are also other lymphatic hyperplasias, and it is very interesting to note that two of WHITE's patients died suddenly in much the same mysterious manner as those succumbing who present the signs of the "lymphatic constitution."

Our knowledge concerning the thymus and its function is practically *nil*, and yet the enlargement and the persistence of this organ in so many conditions, known by different clinical names and appearing as separate entities, can not very well be construed as without significance. It will be remembered that normally the thymus attains its full size at about the second year, and that it remains stationary

until puberty, when it rapidly retrogrades, the lymphadenoid elements becoming displaced by fat and connective tissue, and finally only rests of the original structure remain. The mass of fat and connective tissue that results from this displacement of the thymus, which resembles the shape and the size of the organ, has been called the thymus fat body by WALDEYER.¹⁰

Now, it is singularly significant to observe that OHLMACHER, in four consecutive fatal cases of epilepsy, should come across an uniformly characteristic condition, namely, enlarged, persistent thymus, and a more or less well-marked general lymphadenoid hyperplasia. One of the four cases was found "dead in bed;" the anatomic condition coincides accurately with that found in several other enigmatic diseases that we have mentioned, some of which possess certain clinical analogies. One thing must be quite clear, and that is that somewhere and somehow the peculiar morphologic anomalies found in these cases of epilepsy and noted in thymic asthma, thymic sudden death and exophthalmic goiter, will in the end be found to have something more than a mere accidental bearing upon these diseases. Undoubtedly such observations as those that OHLMACHER has so carefully recorded and analyzed, especially if they are to be duplicated by others in the future, will serve to direct renewed attention to the part played in physiology by that rather anomalous organ, the thymus. One problem that invites continued investigation is the pathologic importance and relation of the thymic and lymphadenoid hyperplasia—the "*constitutio lymphatica*"—encountered in connection with the diseases that have been mentioned.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The annual meeting of this society at Albany on the 25th, 26th and 27th of January, was of more than passing interest in some respects.

Of the forty-five papers read thirty-three were surgical. One evening was devoted to X-rays in medicine and surgery, and four long descriptive papers were read on the progress and technique of this subject. Of the subjects presented medico-legal testimony created some interest; the treatment of insane in the State brought out some comments by evident opponents. The dispensary abuse in New York was avoided, although two parties were present with maps and charts to prove its enormity and the value of dispensaries. Some New York men were trying to promote a scheme to organize a National society of delegates from the State societies alone to meet in Washington yearly to influence legislation. The other topics seemed to call out a great deal of mutual admiration, and were evidently restatements of facts conceded to be correct.

⁵ Correspondenzblatt der Schweizer Aerzte, 1889.

⁶ Ohlmacher, loc. cit.

⁷ Loc. cit.

⁸ International Medical Magazine, 1895.

⁹ British Medical Journal, 1886.

¹⁰ Centralbl. für med. Wissenschaften, 1890.

The usual attempts to exhaust the subject, which usually begins with the introduction of the paper, were noticeable. The encyclopediac writer and the writers who are sure of the physiology, and who describe with startling minuteness most complex operations of nature, and the surgeons whose results are as certain as the repairs of a wagon, were all present. The president's address was an appeal to the profession for higher standards of practice, and a closer relation of social and professional work. It was interesting to note how thoroughly surgery absorbs the present interest of the profession. The great surgeons of New York City are gradually declining, and the inland city and village physician whose post-graduate courses have fitted him for surgical and diagnostic work, are coming into prominence. The writers of text-books and teachers in schools find consultation declining and their income falling off. The rush of specialists to the large medical societies to regain their losing prestige by papers and discussions before the country and general practitioner is increasing. The treatment and practice in large pauper hospitals is misleading, and often very impractical in private work. The results of such treatment when embodied in text-books and elaborate papers, can not be confirmed in private experience and hence confusion follows. Text works by men who never had experience except in hospitals and among paupers are not always good authority.

Physicians who relegate all science to their circles of work and who doubt everything beyond this, are happily growing less every year. State societies fail to be of much use when they confine their subjects to a few topics. When societies become large they should divide into sections where each subject can be treated at some length. The practitioners from the hill countries of New York have diminished interest in the State gatherings of medical men where only certain topics are discussed.

CORRESPONDENCE.

Foreign Correspondence—Vienna Therapeutics.

PARIS, Jan. 29, 1898.

To the Editor:—While Germany is the acknowledged seat of expectancy in therapeutics, the Vienna school, in her attitude toward the effect of drugs in the treatment of disease, is inclined to go a little farther in her unbelief, and approach even the border line of nihilism itself. Nothnagel says: "When called to treat a patient, study the case well, and make the best diagnosis you can. When this is done, never ask yourself this question first: What shall I give this man or woman, but always ask, shall I give him anything?" In a late clinical lecture on a case of chronic atrophic Bright's disease, after describing in a graphic manner the history, symptoms and pathology of the case, he asked: "What shall we give this patient?" His answer was, "Absolutely nothing;" not even the milk diet that he had advised in an acute inflammatory case of the same affection. The next case was one of pleurisy with serous effusion, and in this, excepting advising opiates to relieve pain, and mild counter-irritants to the side, he was equally outspoken in his lack of faith in all medication of whatsoever kind.

Surgically, he would only advise interference if the quantity of the fluid was such as to materially interfere with respiration or the functions of the heart.

"Why is it," he asks, "that after more than a century of existence homeopathy with all its absurdities, still lives, and like Hamlet's ghost will not down. There is but one explanation, that is, that the regular school of medicine injure their patients by the drugs they give them. Is it any wonder that a man with the gonorrhea will seek the advice of a follower of Hahnemann, who will give him a little infinitesimal nonsense which will do him no harm, if no good, instead of consulting a regular practitioner, who would probably put him on the balsam of copaiba, a remedy that will disgust his palate, nauseate his stomach, derange his bowels and irritate his kidneys, but can have no curative effect upon the disease from which he is suffering. If the regular profession had followed the teachings of the Vienna school, homeopathy would have long since died a natural death."

Prof. Störk, in a late lecture on tuberculosis, said: "The treatment of this disease consist in nutrition and hygiene; medicines of all kinds are worthless, unless it be such as may aid digestion and assimilation. Creosote is now the rage, and the poor phthisic victim clings to this dernier hope with all the faith and tenacity with which the crusader followed his flag upon which was painted the sign of the cross. Every now and then you read of cases who have recovered from this disease after taking huge doses of this drug. What is the explanation? It is this; any stomach that can tolerate these doses, can digest food enough to cure the patient, who recovers, not because they took the drug, but in spite of it."

I have visited Vienna at intervals of ten years, and this is my third visit. I find with the lapse of each decade, the treatment of the sick is more and more expectant in character. Twenty years ago, in the treatment of typhoid fever nearly every patient was submerged into a tub of cold water, several times in the twenty-four hours. Now, such a treatment is only carried out in a minority of cases. Though cold sponging is still a general practice, patients are now only regularly tubbed whose temperature is very high, and where such temperature profoundly affects the nervous system.

I saw carried out in one service a plan of tubbing that struck me as rational. It was to put the patient in a bath 2 degrees C. below the temperature of his body, add cold water to this so as to reduce the temperature, 1 degree every five minutes, until 30 degrees is reached, and then allow the patient to remain in the tub ten minutes at this last temperature. No medicines are given with a view of affecting the general course of the disease. If the patient at the outset be constipated a calomel purgative is given, followed by a saline if necessary. After the alimentary tract is thus once thoroughly evacuated all purgatives are thereafter eschewed, the bowels being moved once in twenty-four or forty-eight hours by an enema of cold or tepid water.

The reason assigned for this mode of treatment is that cases do better where the bowels are inclined to constipation, than in those in which there is a diarrhea. Light wines are given during the entire course of the disease and the patient is nourished with raw eggs, milk and animal soups. Great stress is laid on the diet that the patient takes, and he is never allowed an unrestricted one until four weeks after all febrile symptoms have disappeared.

I have tried in a modest way to do a little missionary work in one of the medical services here in Vienna for Dr. Woodbridge's treatment of typhoid fever. I find, however, that my efforts have been an utter failure. I am met with the argument that the disease from earliest manifestation is a constitutional one, the local lesions only playing a secondary role. That while the specific germ that produces the disease first gains access to the blood through the alimentary tract, later on we find this germ

abundantly in the spleen and other internal organs, but only in small numbers, comparatively, in the intestinal tract, so that it was only after the introduction of the Widal method that a diagnosis of the disease through bacteriologic investigation was rendered at all practical, though much labor had been exhausted in the examination of the stools for this germ.

I am surprised, however, to find that in spite of the extensive discussion that this subject has attained in the medical journals in America, not a physician in any of the half dozen hospitals here in Europe to whom I have spoken of the matter, had ever heard of it before.

The treatment of pneumonia is as expectant as possible. The cold applications to the chest, so much vaunted by some of the good men with us, is only used in one of the services here as a regular rule of practice. Expectorants, and especially those of a nauseating character are not used, but if the cough be dry and troublesome, in their stead, tar and eucalyptus is dropped into hot water, and the patient is allowed to inhale the hot vapor from these substances. To relieve the pleuritic pains, Dover's powder is given, and chloral is administered, generally per rectum, to quiet the nervous system and procure sleep. When symptoms of heart failure manifest themselves digitalis, caffeine and brandy are given. In the management of heart lesions Nothnagel eschews all medication as long as circulatory compensation still exists, and is especially emphatic in his opinion that digitalis is of no service and often harmful, until this condition of things appear in the course of valvular lesions of this organ. When, however, edema of the extremities, dyspnea and the like symptoms show themselves, he puts his patient to bed and puts him on large doses of an infusion of digitalis. He uses the remedy for three days, and then discontinues it for two days, and so on. The Oertel treatment of heart lesion by exercise, he only thinks applicable to such cases, where the muscular substance of the heart is involved and not the valves. He does not think that the tinctures and fluid extracts of digitalis are reliable at all.

Speaking of digitalis, I would like to ask the men who read this letter, whether or not they have settled down on a form of this drug that is satisfactory to them, and on which they can rely. If they have, they have been more fortunate than I have been. I have tried them all and have found nearly all equally disappointing.

Some years ago I listened to a series of lectures by the late Germain Sée on the action of this drug in health and disease. They were masterpieces both in a scientific and literary point of view. He discarded all the crude preparations of the plant and relied entirely on the alkaloid digitalin. I followed his teachings for a few years, but often being dissatisfied with the action of the remedy, I abandoned it except for hypodermic use, and have since then tried a variety of its crude preparations.

I was younger then than I am now and I must with some humility and shame acknowledge that I was first induced to drift away from old friend digitalin by one of those long, parrot-tongued agents of one of the thousand and one manufacturing drug houses that infest our country, and are such incorrigible bores to a busy practitioner. Some man who has more brains than they have, write them a little speech; they commit it and deliver it with an unerring accuracy to every unfortunate doctor that they pour down upon. An agent from Cincinnati first struck me. His house produced a tincture from a German grown plant that nothing on earth could equal. After that a babbling agent from Philadelphia, one from Detroit, a horde from St. Louis invaded my sanctum one after another, and like Eve I lost my head and was tempted and led astray by the sweet voices and charming manners of these unscrupulous commercial agents. Seriously, I believe that the stuff that these men are selling to a large number of our physicians, especially the younger ones, including as it does ready-made and compounded remedies for all imaginary diseases, is one of the worst

stumbling-blocks in the way of a true advancement in the line of therapeutics.

Huchard, in a late number of *Le Journal des Praticiens* treating of this subject, discards all crude preparations of digitalis on account of their variation in strength, and uses digitalin alone. He claims that all cultivated specimens of the herb are next to worthless.

I have spent twenty months in Vienna, and have been a pretty constant attendant at one or the other of the two surgical clinics here. I believe that approximately I have seen 800 patients anesthetized during that time, and of these four have died on the table from the effects of the anesthetic. The agent used was always either pure chloroform, or that even more dangerous compound in my opinion, the A. C. E. mixture.

Among the early axioms that I learned as a medical student was one that said statistics *never lie*. I believe now, however, that that proverb has been revised, and it is now safe to assert that statistics *always lie*. I am sure they lie and lie awfully in regard to the mortality following the use of chloroform as a general anesthetic; for those given by Dr. Andrews show such a mortality to be only one in 5000, while my observation shows a mortality of one in 200. In spite of the facts in the case which I believe will show, as Dr. Da Costa of Philadelphia wrote me, that chloroform is ten times as fatal in its effects as ether, in answer to the question as to whether the surgeon used chloroform or ether, sent out by me to a large number of surgeons in the United States, shows that three-fourths of those living west of the Mississippi River use the more dangerous agent.

What strikes me as strange, and may account for the terrible mortality of chloroform here in Vienna, is the fact that no attention is paid as to the position the patient occupies while under the anesthetic. Both the patients I saw die this winter were in a semi-erect position when the first fatal symptoms were manifested. Briefly the history of the last case was this: A healthy looking man, aged 51 years, was brought into Professor Gussenbauer's amphitheater to be operated on for a recurring sarcoma in the right maxillary region, and in which it was necessary to remove a large portion of the superior maxilla, and the outer third of the inferior maxillary bone. The patient was placed in a semi-erect position, the A. C. E. mixture was given, and when the operation had continued about thirty minutes and was about half finished, he ceased to breathe. The patient was now hurriedly placed in a horizontal position, a brisk stream of cold water was thrown from a height on his bowels and chest, artificial respiration was resorted to and kept up for two or three minutes. As no amelioration in the patient's symptoms seemed apparent at the end of this time, a tracheotomy was rapidly done, a tube introduced and Professor Gussenbauer sucked out about a drachm of blood from the trachea. A rubber tube was now introduced into the tracheal tube, and through this was thrown a gentle stream of oxygen gas. During all this time artificial respiration was kept up, and the stream of cold water kept playing on the bowels and stomach. Only at the end of thirty minutes were these futile efforts at the resuscitation of the patient abandoned. No hypodermic of either nitroglycerin, strychnin or brandy were tried.

Of all the surgeons I have ever seen operate Gussenbauer is the most painstaking in his efforts to save his patients from the loss of blood. Even in an ordinary laparotomy he ties from six to twelve blood vessels before he opens the peritoneal cavity. On the other hand, Pozzi, whose work I am now following, never ligates a vessel in the abdominal wound in doing the same operation.

In the case of the removal of the breast and axillary glands I saw Gussenbauer tie 107 blood vessels, in which case most surgeons would have tied only one-fourth of that number.

Fraternally yours,

W. S. CALDWELL, M.D.

The Appendicitis Question.

DETROIT, MICH., Feb. 14, 1898.

To the Editor:—It has been a rule in my life never to go into a controversy with people, although I have sometimes sent communications to the JOURNAL, giving my views when I disagreed with others. My friend from Richmond, Ind., has sent a long reply to my last communication, and, after carefully reading it, I have come to the conclusion that he is a nice, good fellow and a progressive physician at heart, and if we bring our views together I am sure we will perfectly agree, excepting on some minor details.

He quotes Treves and Thalamon, both of whom had limited experience with the operation of appendicitis, and whose opinions should not count alongside of such men as Robert Morris, J. B. Murphy, Joseph Price, Fowler and Deaver, men who have had hundreds of operations and seen the terrible results of procrastination. When a man who has operated ten, twenty or thirty times and who has had bad results, because he has not learned the *minute detail* of the operation, says you should not operate before the tenth day, except on those cases where a large abscess has formed, which is well walled in and which simply needs to be opened (which any tyro in surgery can do), but who, at the same time, allows a dozen other patients to die on the second, fourth, sixth or eighth day, when such men give their views *they do more harm than we do* who are obliged to take the other extreme.

It depends upon who operates. Often the surgeon, himself, infects the parts that are clean and the patient dies as a result of the operation, but a good abdominal surgeon, with perfect asepsis, will seldom have a patient die before rupture and general peritonitis, except as the result of some unforeseen accident. Ideas are charged to me which I never held nor expressed. There are any number of cases where I refused to operate because I saw the patient was convalescent, but said that if they had recurrence they should have an operation performed the first day. It is easy to say you will operate at the interval, but patients, if they feel perfectly well, will not submit to an operation at the interval, for which I do not blame them, as, they say, "perhaps I will never have another attack."

The other point is diagnosis. Some men can never diagnose a case of appendicitis, or only in rare cases. My views are not expressed on cases where a diagnosis had not been made. I do not operate by guesswork. I assume, in my communication, that diagnosis is made and that, with a rare exception, it can be made in the first twenty-four hours, before rupture has taken place. I am sure the Doctor will agree with me that it is better to operate the first day, or, for that matter, the second, any time before rupture has taken place. That is all I claim. I will admit if you have a fortunate case, where the rupture and the resulting abscess is well walled in and gradually works its way outward, and in the course of ten or fourteen days points at some place near the crest of the ilium, that it is easy and not dangerous to open that and let out the pus. At the same time, before this takes place, in many cases it ruptures into the peritoneal cavity, we have general septic peritonitis, or, the absorption of septic material is so great that your patient dies (in either case) on the fifth or sixth day. So that the controversy stands really here:

My friend will accept the dictum of a general surgeon with a very limited experience in abdominal surgery, like Treves, or some young man, also with a limited experience, like Thalamon, while I prefer the views of men who have operated on a couple of hundred cases each, like Price, Deaver, Murphy, Fowler, Morris and others.

1. He and I agree that a diagnosis should first be made.

2. He and I agree that a convalescent patient should not be operated upon.

3. He and I agree that patients absolutely recover without recurrence and without an operation.

4. He and I also agree that some patients need an operation, and if there is any difference in our views it is simply as to when is the best time.

I believe, with my limited experience, as I see only about fifty cases a year, that the greatest number of patients will be saved if they would all be promptly operated upon as soon as the diagnosis is made. So that, after all, we get so near together that there is no use splitting hairs about it, and I am perfectly convinced that Dr. Haughton is a nice, good fellow, that he means well, and what is more, I am sure he is progressive and wants to arrive at the truth, otherwise, we would never have heard from him. Yours truly,

J. H. CARSTENS, M.D.

The Australian Eunuchs.

CHICAGO, Feb. 10, 1898.

To the Editor:—In an article on "The Oriental Eunuchs," by Dr. Edmund Andrews, in the issue of January 22, in the paragraph on "Australia" the author refers to the natives limiting "the increase of families by crushing the testicles of the father after his first child is born." Referring to this point the facts below are not entirely relevant, but may prove of interest in this connection.

My brother, Mr. Fred Hessert, who has for over a year been sojourning in West Australia, has in his letters to me described some of the customs of the barbaric natives. Owing to the barren desert condition of the country, the natives prevent a too great increase in their number by certain surgical operations performed on the penis. When a boy reaches the age of puberty he is taken in hand by a number of old "bucks," who lead him into the "bush" and there perform on him an external urethrotomy. The opening is made with crude instruments, sharp stones, pieces of tin or old knives and the like obtained from the whites. The opening is made at the beginning of the *pars pendulosa* and is kept open so that eventually a fistula is produced. The object of this procedure is evident; in copulation the semen is ejected through the fistula and the possibility of impregnation reduced to a minimum. When the black desires to impregnate, he plugs up his fistula with a gum or resin obtained from a certain tree. The plug he keeps in place with a few turns of dried grass or vegetable fiber and he again becomes a potent factor.

Another operation that is practiced is to slit up the entire urethra from the perineum anteriorly. This is more radical, and permanently prevents the possibility of impregnation.

These operations are commonly practiced in West Australia at least, and inasmuch as the letters from my brother are exhaustive and in detail, and no mention is made of castration, I would infer that the latter procedure is practiced but very rarely in that region.

As the natives, even in the cold season, are very scantily dressed observation at this point is easy.

Respectfully yours, WILLIAM HESSERT, M.D.

How Squirrels Become Eunuchs.

HAYNEVILLE, ALA., Feb. 10, 1898.

To the Editor:—In the JOURNAL (Feb. 5, 1898) I read a communication from Dr. Eugene S. Talbot on the subject "Do Adult Squirrels Castrate Each Other?"

Castrated Squirrels are frequently killed in this country, and the supposition is almost universal that the operation is done through motives of jealousy in desperate combats.

This is one of the zoological fictions belonging in the same category with the horsehair snake.

The missing testicles have been destroyed by a parasitic worm peculiar to those organs of the *sciuri* family.

Yours, C. E. MARLETTE, M.D.

Oxytuberculin.

SANTA CLARA, CAL., Feb. 9, 1898.

To the Editor:—In regard to the "Oxytuberculin" treatment for consumption it is but just to the medical profession at large to comment on the other side. Any treatment which will not bear inspection can not be of much value.

It is a very loticeable fact that all of the cases seem to be diagnosed by one individual, viz., Dr. Hirschfelder. These cases are not presented to the unbiased medical profession for diagnosis before treatment. It is only after an alleged cure or "great benefit" that they seem to be exhibited. Nothing is said about the diet during treatment, which is a matter of very great importance. A patient suffering from tuberculosis, if placed upon a generous diet together with good hygienic conditions and a promise of complete cure, will frequently improve very rapidly. During such improvement, the bacilli become scarce or absent from the sputum. Such a patient may remain well or may succumb to the disease years later. No individual is justified in claiming a cure until at least two years have elapsed without any symptoms of tuberculosis whatsoever.

Living within a few miles of the producer of "Oxytuberculin," I have had opportunity to witness its use in a number of cases. In but one case has there been any apparent benefit. That was a case of asthma and no positive evidence of tuberculosis at all. The case has been reported "cured." No such results are obtained outside of the clinical department of Dr. Hirschfelder and his immediate professional friends as he reports from the inside.

It would appear that the "investigation" by a committee from the faculty of Cooper Medical College was a sort of star-chamber performance at which all medical men liable to be incredulous, inquisitive or over particular about details were excluded. Apparently it was a sort of love-feast participated in by the Faithful. Taken, in all, there seems to be much assertion and but little evidence that any one has been cured by oxytuberculin rather than by natural forces inherent in the human body, aided by good food and nursing.

Yours respectfully, E. H. SMITH, M.D.

**A Correction of Dr. Charles Denison's Article:
"The Antitoxic Treatment of Tuberculosis."**

CHICAGO, Feb. 14, 1898.

To the Editor:—Dr. Charles Denison enumerates in the above mentioned article the different therapeutic products obtained from cultures of tubercle bacilli: the tuberculin Koch, the tuberculocidin and antiphthisin (Klebs). As No. 4 he gives "tuberculinum purificatum, which name Dr. Karl v. Ruck of Asheville has given to his manufacture of practically the same preparation." In a foot note the manner of preparation of the last is given, absolutely identical with the method published by me in 1894 for the preparation of tuberculocidin.

As Dr. von Ruck, so far as I know, has never published the formula of his "tuberculinum purificatum," I can not say if Dr. Denison is in error or if Dr. von Ruck has brought on the market a preparation the same as tuberculocidin, simply using another name. Probably the first suggestion is the correct one, but the profession should be enlightened on this point by Dr. Charles Denison, Denver, or Dr. Carl von Ruck, Asheville, N. C.

EDWIN KLEBS, M.D.

The Idaho Medical Practice Act.

BOISE BARRACKS, IDAHO, Feb. 8, 1898.

To the Editor:—The item in the JOURNAL for January 29, announcing that the supreme court of this State had declared the medical law unconstitutional because it had passed the

senate irregularly, is calculated to create a wrong impression among those who should know the facts.

The bill was passed regularly, but the journal of the senate, which should have stated "the bill was then read a third time in full by sections and passed," simply stated, "the bill was then read a third time and passed." The constitution of the State was complied with but the journal was incomplete. On this technicality the bill was pronounced unconstitutional. Verily, on what a slight thread hangs the fate of medical legislation, even after as long and stubbornly fought contest as that by which our "dead" law was procured! Very truly yours,

M. W. WOOD,
Chairman Committee on Legislation Idaho State Medical Society.**Tubercle Bacillus.**

WARREN, PA., Feb. 12, 1898.

To the Profession:—Any physician knowing of cases in which tubercle bacilli were found in the sputum, without any other physical evidence of disease in the lungs, and having seen such cases for a period of several years, noticed no further progress of the disease, will confer a great favor on the undersigned by reporting the same to him. I desire to obtain evidence on the import of bacillus tuberculosis in the sputum.

M. V. BALL, M.D.

PUBLIC HEALTH.

Progress in Formaldehyd Disinfection.—For two years the Chicago Health Department has been investigating the claims made for formaldehyd as a disinfectant with especial reference to the practicability and value of its use for household or domestic disinfection. For this latter purpose the following requirements must be met: 1. A light portable apparatus of simple construction and easy manipulation. 2. The evolution of a quantity of the gas in from one hour to an hour and a half sufficient for the area to be disinfected. 3. The killing of a majority of all non-spore-bearing bacteria, both in a moist and in a dry state, in a six-hour exposure, and some degree of penetration in this time. 4. Reasonable cost of disinfection per 1000 cubic feet. These requirements are made necessary by the conditions under which most of the department disinfections are made. The greater number are in the poorer districts of the city, where the dwellings and apartments are of loose construction and not uniformly warmed in cold weather. As a rule, the tenants continuously occupy the entire space at their command and on this account they are not infrequently obliged to walk the streets until the disinfection is completed. The time most available is during the middle of the day, and the rooms must be opened in time for the preparation of the evening meal. The great extent of the city, requiring the disinfectors to travel long distances, precludes any heavy or cumbersome apparatus, and the operators are not sufficiently skilled as mechanics to operate valves, thermometers and gauges with which many of the appliances tested are furnished. As all manner of articles are to be disinfected, including clothing, bedding and even kitchen utensils, the disinfecting agent must show reasonably destructive properties toward all kinds of bacteria cultures exposed and especially toward the pathogenic varieties. Every known form of formaldehyd disinfectant has been tested during this period, including four using methyl alcohol, two using formochloral, one for the combustion of paraform pastils, and a number using formalin and special compounds. Without going into details at this time the statement may be made unqualifiedly that no apparatus or method thus far tested has fully or even fairly met the requirements deemed essential for municipal disinfection, as above enumerated. Quite recently, however, a device for the vaporization of formalin, in an open vessel containing asbestos chips

or fiber, was brought to the notice of the Commissioner, and the tests of this device, ordered by Dr. Reynolds and conducted under Dr. Gehrmann's supervision, have led to a still further simplification of the apparatus and more recently to the use of formalin diluted by the addition of three times its volume of water. The simplified apparatus consists of a shallow granite-ware vessel, of half-gallon capacity, supported over a methyl-alcohol lamp, capable of holding twelve to sixteen ounces of the wood spirits. The asbestos has been found unnecessary, since it does not prevent the conversion of a larger percentage of the formic aldehyd into inert paraform than when it is not used. Tollens and Mayer had already demonstrated that the polymerization of formic aldehyd 'does not take place with water at 100 C. when in dilute solution, and the results of Dr. Gehrmann's experiments on this line show that whatever amount of polymerized aldehyd may be formed during the concentration resulting from vaporization can be re-converted into the simple form by a further addition of boiling water. One pound of the formalin solution of 40 per cent strength contains, approximately, 200 grams of formic aldehyd and, as from 30 to 50 grams are sufficient for the disinfection of 1000 cubic feet of space, one pound of the solution should be sufficient for the treatment of 4000 cubic feet, provided all the formaldehyd can be vaporized. In practice the experiments thus far conducted show that by diluting the ordinary solution with three times its volume of hot water and then boiling for half an hour, from 40 to 50 grams of the gas will be disengaged, quite sufficient to disinfect 1000 cubic feet. Whatever paraform is produced may be utilized for the next disinfection by the addition of boiling water; thus there is no waste. A six hours' exposure under these conditions has given better results in the sterilization of cultures than has been obtained by any other method, and the other requirements, simplicity and portability of apparatus, rapid evolution of the disinfecting agent and brief duration of exposure, together with reasonable cost of disinfection, are also more nearly met. The results have, indeed, been so satisfactory and the remarkable bactericidal properties of formic aldehyd have received confirmation in such a practical manner through these experiments that, at the suggestion of the Assistant Commissioner, Dr. Reilly, an inexpensive vaporizer has been devised by Dr. Jaques, chief of the diphtheria corps, for use in the room occupied by a diphtheria patient during the case. This vaporizer consists of a shallow cup supported over an ordinary cheap lamp, such as is made for coal-oil or kerosene. Methyl alcohol is used for the flame. The cup is nearly filled with a solution consisting of about one part of 40 per cent. formalin and five parts of boiling water. The flame is so adjusted as to keep the solution just at the boiling point. The device in use costs less than twenty cents. This is furnished and used in all charity cases of diphtheria treated exclusively by the department, and is believed to be useful in limiting the danger of spread of the contagion to attendants and others, and to effect some degree of continuous disinfection of the room and its contents during the progress of the case.

The Calvary Bill.—The Senate Committee on Public Health and Quarantine at Washington has submitted to that body, through Senator Vest of the committee, a report upon the various plans which have been referred to it for the creation of a Department of Public Health. As might have been anticipated from the constitution of that committee, the report is wholly in the interests of the Marine-Hospital Service, which, with the powerful support of the Treasury Department, has better facilities for persuading Congressmen than can be enjoyed by any interest or interests distant from Washington. The Marine-Hospital Service was established in the Treasury Department for the sole purpose of caring for the sick sailors of the merchant marine. Such hospitals were once necessary

because the general hospitals were few and hardly sufficient for the needs of the permanent population in their vicinity; but the seaport cities have now hospital accommodations large enough to receive the ordinary sailors, while those attached to the navy would naturally be still cared for in the hospitals of that service. Under a succession of energetic chiefs the Marine Hospital has acquired functions foreign to its organization, and now demands the oversight of the public health work of the nation, a function not justified by anything in its constitution or experience. If any existing department in Washington could be properly placed in charge of our quarantine work, the navy would seem to be the proper body, for its medical officers have visited all quarters of the globe and are more familiar than any other public servants with the foreign diseases which produce so much disturbance when introduced into this country. The great sanitary need of the country, however, is something of far greater importance than a quarantine against yellow fever or cholera. The disgraceful deficiency of the government at Washington in this regard lies largely in the fact that a few cities and less than five States have done the only creditable public health work of the country in later years. It has been the hope of many that the growing belief in really scientific methods for the prevention of disease might find some encouragement in the halls of Congress; but it now seems probable that the same Senate is willing to hamper the methods of investigation which have given us a means for controlling diphtheria and to enlarge the powers of the Marine-Hospital Service for the sole purpose of creating a quarantine against yellow fever and cholera alone. The larger part of Senator Vest's report, which accompanies Senate Bill No. 2680, is devoted to the discussion of the constitutional right of the United States to protect its inhabitants against a contagious disease introduced into this country from abroad; and, fortunately, the conclusion is reached that the general government has that right, but it hardly seems necessary at this late day to spend much time upon the question of a right to save human life when Congress has more than once authorized more drastic measures for the suppression of diseases among the domestic animals than any now demanded for man's protection. So long as the Senate regards its associate from New Hampshire, Dr. Gallinger as a sufficient representative of the present views on preventive medicine, we are not likely to get any better plan for a public health service than this presented by Senator Vest; but if any of our readers are in a position to do missionary work in instructing any Senator in the beneficent functions of the great sanitary boards of other countries, let such hasten to the task.—Editorial in *Boston Med. and Surg. Journal*, February 10.

Origin of the Fever of 1897.—The committee of the legislature of Mississippi, which went to Ocean Springs, in that State, recently for the purpose of investigating the origin of the yellow fever, with which the Southwest was afflicted last summer and fall, reports that the epidemic did have its origin in that place, but that it was not brought there from the Marine-Hospital Service quarantine, as has been charged, or by Cuban filibusters who fitted out a filibustering expedition there in the early part of last summer, but that it was introduced there from Guatemala by a Mississippi family that had been temporarily staying in that country. The family came to this country on the steamer *Breakwater*, and reached Ocean Springs early in April. None of their baggage was disinfected. Soon after their arrival at Ocean Springs one of their number became ill with fever. Within a few days other cases of fever made their appearance in the vicinity of the first case, and fever of some character prevailed at Ocean Springs all summer, though it was not until September that it was diagnosed as yellow fever. In all the Southern ports strict quarantine goes into effect on May 1. It is apparent, if this report of the committee of the

Mississippi legislature is to be relied upon, that strict quarantine against yellow fever countries ought to go into effect much sooner, because it was in April that the disease was introduced into Ocean Springs. In this connection it is recalled that it was in March that the *Emily B. Souder* is said to have introduced the yellow fever into New Orleans March, 1878, the year of the great epidemic of yellow fever in the Mississippi Valley. If what is said in respect to the origin of the fever last year and 1878 is correct, it is evident that the disease can be introduced into a port in comparatively cool weather, that it may linger there months and finally develop into an epidemic under favorable conditions when the hot weather comes. The conclusion is that all the South Atlantic and Gulf quarantine officers ought to be on the lookout for the fever all the year around, and that the quarantine regulations at all these ports ought to be uniform, and strictly enforced by competent men. —*News*, Savannah, Ga., February 5.

ASSOCIATION NEWS.

Chicago Gynecological Society.—The Chicago Gynecological Society entertained the Trustees of the AMERICAN MEDICAL ASSOCIATION, the evening of February 18, in the Stewart Building. The following program was presented: Exhibition of specimens; exhibition of instruments; report of cases; "The Removal of Fibroid Tumors of the Uterus without Hysterectomy," by Dr. E. E. Montgomery of Philadelphia; "Vaginal Hysterectomy and Igni-Extirpation," by Dr. Joseph Eastman of Indianapolis; "The Rectal Reflexes in relation to Gynecologic Work," by Dr. J. M. Mathews of Louisville; "Uretero-vaginal and Uretero-abdominal Fistulæ," by Dr. A. H. Ferguson.

Collation. The guests of honor were Alonzo Garcelon, M.D.; G. C. Savage, M.D.; I. N. Love, M.D.; E. E. Montgomery, M.D.; J. M. Mathews, M.D.; C. A. L. Reed, M.D.; Joseph Eastman, M.D.; J. T. Priestley, M.D.; Truman W. Miller, M.D.; John B. Hamilton, M.D.

SOCIETY NEWS.

New York State Medical Society.—The Society convened in annual session at Albany January 25. Among the papers of general interest was one by Dr. William Warren Potter of Buffalo, President of the State Medical Examining Board, entitled "Medical Education; the State License to Practice Medicine." Dr. John H. Pryor, also of Buffalo, presented a paper on the duty of the State and county in reference to the treatment and care of consumptives. He advocated the establishment of a colony for consumptives upon State lands in the Adirondack region. "The Hygienic Management of Dairies," and "The Municipal Control of Milk Supply in Cities and Villages, with Report of Health Regulation," were read by Dr. E. F. Brush of Mt. Vernon and Dr. W. H. Heath of Buffalo, respectively. Dr. Heath's paper recommended quarantine in the dairies from without, carefulness in issuing dairy licenses and legislation requiring sanitary conditions in transportation. He also advocated the plan of not allowing small grocers to handle milk, as much disease undoubtedly lodged in the fluid while in those places, since these people neither know how nor are able to properly store the milk. Other papers were read pertaining to the diseases of women by R. J. Wilding of Malone, Herman A. Hayd of Buffalo, Edwin B. Cragin of New York, W. E. Ford of Utica, J. Riddle Goffe of New York. Papers were also read by George M. Edebohls of New York, M. D. Mann of Buffalo and J. E. Walker of Hornellsville, and Dr. P. M. Wise had a paper on "The Past, Present and Prospective Methods of Treatment of Insanity in the State of New York." Other papers were: "A Year's Work in Appen-

ditis," Herman Mynter of Buffalo; "Lessons from Six Cases of Appendicitis," William B. Jones of Rochester; "Congenital Dislocation of the Shoulders Backward, with a Report of Seven Cases and an Operation for its Relief," A. M. Phelps of New York; "The Treatment of Rachitic Deformities," Reginald H. Sayre of New York; "The Management of Undescended Testicle in Hernia Operations," William B. DeGarmo of New York. The following officers were elected: President, John O. Roe of Rochester; vice-president, E. F. Brush of Mt. Vernon; secretary, F. C. Curtis of Albany; treasurer, Charles H. Porter of Albany. Drs. Frank Van Fleet of New York, Arthur G. Root of Albany and Ernest Wende of Buffalo were appointed a legislative committee.

Salt Lake County Medical Society.—At the last annual meeting of the Salt Lake County Medical Society the following officers were elected for the ensuing year: Philo E. Jones, president; George H. Penrose, vice-president; E. I. Thorne, treasurer; H. S. Scott, secretary. This is the oldest medical society in the intermountain region and has a membership of seventy. The Society's meetings are held the second and fourth Monday evenings of every month.

NECROLOGY.

JOHN CROMYER, M.D., University of Toronto, Canada, 1852, died at his home in Buffalo, N. Y., February 11. He was born December 22, 1825 in Black Rock, a suburb of Cork, Ireland, and in 1837 came to this country. In 1859 he removed to Buffalo, where he became widely known as a medical scholar, apt debater and the possessor of many attractive qualities. He was a member of the AMERICAN MEDICAL ASSOCIATION, a founder and ex-president of the New York State Medical Association, to the reputation of whose series of Transactions he annually contributed in various ways, and he was besides for many years an honorary member of the Ontario Medical Association.

GEORGE C. BRIGGS, M.D., University of Michigan, Ann Arbor, 1853, died from cardiac disease while driving to his home in Burlington, Vt., late on February 11. His horse brought his body to his door. In 1876-77 he was professor of materia medica in the University of Vermont and in 1873 was representative for the town of Franklin in the Legislature. Besides he was a leading member of the Vermont State Medical Society and consulting physician of the Mary Fletcher Hospital in his residential town.

FREDERICK L. VON SUESSMILCH, M.D., Delavan, Wis., a native of Hanover, Germany, died February 10, aged 77 years. He participated as surgeon in the civil war, being attached to one of the Wisconsin regiments. The city of Delavan has repeatedly elected him mayor, and he was for many years a member of the State Board of Health. He was graduated from the Royal Medical and Surgical College, Dresden, Saxony, in 1848.

G. A. WILDER, M.D., one of the oldest physicians of Circleville, O., died suddenly January 30. Dr. Wilder served for many years on the Board of Education and was a member of the Pension Examining Board under President Cleveland. He graduated from the Berkshire Medical College, Pittsfield, Mass., in 1864.

WILLIAM H. HELM, M.D., University of Pennsylvania, 1864, of Sing Sing, N. Y., died February 5.

THOMAS H. ATKINSON, M.D., Jersey City, N. J., February 4, aged 26 years.—**M. E. Connolly, M.D.**, Dubuque, Iowa, February 2, aged 54 years.—**Christian W. Delleubaugh, M.D.**, Cleveland, Ohio, February 3, aged 68 years.—**Ira E. Lyons, M.D.**, Huntington, Ind., aged 76 years.—**T. T. McDonald, M.D.**, New Carlisle, Ind., February 7, aged 66 years.

DEATHS IN THE MEDICAL PROFESSION ABROAD.—Dr. Filippo Lussana, Emeritus Professor of Physiology in the Universities of Parma and Padua.—Dr. G. Alexianu, Professor of Medical Pathology at Bucharest.—Count Motta Maia, Professor of Anatomy and Operative Surgery in the Medical Faculty of Rio de Janeiro.—Dr. Francesco Bini, for many years Professor of Psychological Medicine at Florence, aged 84 years.—Vallin, Professor of Clinical Surgery at Lille, France. Translator of Greig Smith's large work on Abdominal Surgery and author of numerous articles in this line. Physician to the pilgrims at Lourdes. Death in early prime from small anthrax on the wrist, contracted professionally.—Professor Zacharjin, Moscow, the famous Russian who devoted all his earnings as professor to founding scholarships for poor students. Although frequently summoned to the nobility he retained his simple, brusque manners to the last. When the Czar Alexandria III. was on his death bed, Zacharjin scandalized the Court by his dressing gown and farmer's boots which he wore everywhere. He gave his services freely to the poor but the rich had to pay high for them; his fee for consultation in certain families was 10,000 roubles. In one case he received 25,000 roubles for a single visit to the manufacturer Karetnikow, who also placed a special train at his disposal.

MISCELLANY.

The Ninth International Congress of Hygiene and Demography will convene at Madrid, April 10 to 17, with an exhibition of articles of interest in these lines. For particulars address Dr. Amelio Gimeno, Ministerium de la Gobernacion, Madrid, Spain.

Correction.—In the JOURNAL of January 22, page 202, column one, seventeenth line from the bottom of the page, "rather than how" should read "rather than low"; also line thirty-two from top, "optical instruments" instead of "optic instruments."

A Cordial Spirit.—Convalescent (dictating): Please say to Mrs. Jackson that I thank her, not alone for the brandy peaches that she so kindly sent me, but for the spirit in which they were sent.

Bismuth Capsules; a New Application of the Roentgen Ray to the diagnosis of gastro-intestinal affections. An ordinary gelatin capsule (2.25 by 1.25 cm.) is filled with a non-toxic substance, opaque to the rays (metallic bismuth) and swallowed by the patient. Its varied course throughout the alimentary canal can then be followed with the fluorescent screen or by radiographs. It casts a clear shadow and the importance of the information thus derived in various affections of the stomach and bowels is evident, and also in the study of the effect of various medications upon the peristalsis, etc., of the gastro-intestinal tract. The capsule is arrested and lingers for days where there is stenosis of the pylorus or intestines. The interesting communication on the subject in the *Deut. Med. Woch.* of January 13, is from the eminent authorities, I. Boas and M. Levy Dorn of Berlin, who have tested the capsule on fourteen persons and regard it as a valuable contribution to the study of these viscera from many points of view. The capsule is coated with celluloid to keep it from dissolving and is stained a bright color to enable it to be readily detected in the feces. Powerful rays and a high tension current are needed, and it is well to note whether the shadow is more distinct from the front or rear. With much obesity, they found it impossible to trace the capsule lower than the stomach. In the majority of cases it was found either in the greater curvature, near Bauhin's valve or in the cecum. They never happened to witness its passage through the pylorus. In several cases of slight gastric disturbance the capsule was found after twenty-four hours, invariably

in the cecum; less time was required for it to pass through the small intestine to the cecum than for its passage through the pylorus. They are now searching for some substance to coat the capsule that will allow it to be dissolved at will by a chemie agent. They conclude by stating that henceforth a neoplasm or constriction requiring operation can be located with precision by having the patient swallow a capsule as a preliminary to the operation.

Embalming Crushed Members; "No More Traumatic Amputations."—Several of our exchanges have recently been extolling the favorable results attained with Reclus' embalming process (*Rev. de Chir.*, January, 1897), in the traumatism in industrial establishments, etc., as it saves the maximum of tissue and ensures the best stumps or an available member. Even from Chile comes the same cry of the increasing numbers of these accidents: "scarcely a day passes here in Santiago in which our *sui generis* suburban line does not crush the ankle or arm of some unfortunate," and the conservative embalming process is frequently practiced with most gratifying success (*Revista Medica*, October). The *Journ. d. Sc. Méd. de Lille*, December 25, describes the case of a woman eight and a half months pregnant, whose hand had been crushed in some machinery. For several days the hand was plunged for hours at a time in phenicated and disinfected hot water. Then a few whiffs of chloroform were given her and the toilet of the hand accomplished with quantities of very hot water and with solutions of sublimate and potassium permanganate, removing the loose projecting fragments of bone. Small squares of soft gauze impregnated with a poly-antiseptic salve consisting of all the substances currently used in surgery (less of those easily absorbed: sublimate, phenic acid and iodoform, and more of the others, boric acid, salol, antipyrin), were carefully fitted into every crevice, covering the hand entirely, completing the dressing with a thick layer of cotton and a tight, compressing bandage outside of all, to secure anastomosis of the vessels. The patient then left for a maternity where she underwent a normal confinement. The embalming dressings are never touched for three weeks, leaving to nature the task of separating the dead from the living tissues. When they were removed in this case, after twenty-six days, under a thick layer of a fetid, chocolate-colored fluid, the wounded surface was found covered with healthy granulations, with the necrosed parts entirely eliminated. An autoplasmic operation was performed a week later, which healed rapidly.

A New Conception of Artificial Immunity.—Ehrlich has suggested that possibly intoxication by a special toxin may be due to the combination of the toxin with certain cells of the organism. According to this idea the antitoxins are nothing else than the constituent parts of normal cells constantly eliminated, constantly regenerated, in the course of the immunizing process, which neutralize the toxin circulating in the blood, thus protecting the organism against its injurious action. Wassermann and Takaki have been experimenting in this line and they find that they can neutralize a fatal dose of tetanus toxin by injecting healthy brain matter. Their premises are that if the antitoxin of tetanus is derived from the cells of the central nervous system as we have reason to suppose, it should exist normally in the brain and medulla. We can consequently confer immunity by introducing into the system nerve substance from these organs taken from healthy animals. These suppositions were confirmed by experience. Fragments of the brain and medulla of healthy animals, emulsified in physiologic salt solution, were mixed with a fatal dose of tetanus toxin and the mixture injected into white mice, which are particularly susceptible to tetanus. No effects from the toxin were observed. A preventive injection of the brain emulsion several hours before the tetanus toxin was administered, also saved the animal from its effects. This power is more marked

in brain matter than in the medulla. It is inherent in the cells themselves, as the centrifugalized fluid is without it, and also the serous fluid of the cerebral ventricles, and emulsions of other organs, spleen, kidney, spinal cord, etc. These facts, with the results of clinical observation, seem to show that the tetanus toxin has a special affinity for certain groups of cells of the nerve centers. This affinity exists not only between the toxin and the living nerve substance, but for nerve substance taken from the brain and medulla of dead animals. When an emulsion of these organs is injected with or before the tetanic toxin, the latter combines with the nerve substance circulating in the blood and is thus neutralized. Wassermann's experiments suggest a new style of opotherapy: to determine for each bacterial toxin the special organs for which it has an affinity, and protect the organism by injecting emulsions of this organ derived from sound animals.—*Berl. klin. Woch.*, January 3.

Tubal Pregnancy and Vaginal Celiotomy.—Dürhssen contributes a study of this subject to the *Arch. f. Gynæk.*, Vol. xiv, No. 2, describing his technique in full, advocating the vaginal route, as the operation is less severe, without shock, or consecutive necrosis or suppuration, and the patient recovers rapidly. He has operated on fourteen in this way, all anemic. Eleven recovered by the twelfth day; one died soon after leaving the hospital; one had such hemorrhage that the operation was supplemented with vaginal hysterectomy. In another there was a secondary suppurating hematocoele. In his nineteen abdominal operations, there were two deaths, two secondary suppurating hematocoeles, and one secondary consecutive to the operation. He proceeds the same whether the tube is or is not ruptured: 1. He opens into the abdominal cavity through the anterior cul de sac. 2. Draws down the fundus of the uterus into the vagina with Museux forceps, and then the diseased tube. The peritoneal adhesences are usually easily detached. 3. Ligature in stages and section of the adnexa with the thermocautery. 4. He replaces the uterus in the abdominal cavity and closes, separately, the peritoneum and the vagina. If the uterus is retroflexed, he performs vaginofixation. As far as possible, no drainage. Thus performed, vaginal celiotomy does not interfere with future normal pregnancies. He considers that every tubal pregnancy in the early stages should be extirpated as soon as the diagnosis is established. Anemia is not a counterindication, but he prepares anemic patients by injections of artificial serum immediately before operating. He ascribes the etiology to peritoneal adhesences consecutive to perisalpingitis, modifying the shape and direction of the tube, or to catarrhal inflammation of the tubal mucosa, generally of gonococcic origin, which arrests the peristaltic movements of the tube, with the loss of the cilia of the cells. The passage of the fecundated ovum toward the uterus is thus hindered, while the same factors favor the penetration of the spermatozoon. He also admits the possibility of a puerperal atrophy in nursing mothers which would favor the development of tubal pregnancy. —*Presse Méd.*, December 25.

Physical Treatment for Obesity.—W. Kinternitz reviews the disadvantages of the various antifat methods in vogue in an address reported in the *Therap. Woch.*, of December 12. He states that they are all more or less weakening, underfeeding, with occasional after-results such as disturbed digestion, neurasthenia, etc., while the use of the thyroid tablets has been followed in numerous instances by serious disturbances of the circulation and nervous system, and even diabetes. He prepares the patient by a preliminary course of training of the vessels all over the body, by mechanic and thermic stimulation. He accomplishes this by reducing the temperature by a cold bath lasting fifteen minutes, more or less, followed by the "reaction promenade," which by muscular exertion raises the temperature again to normal, but does not produce the exces-

sive heat it would if it had not been preceded by the cold bath. He also uses massage and dry packs in certain cases, individualizing in all, and repeating the process of withdrawing the heat of the body and the reaction warmth production two or three times in the twenty-four hours. A valuable adjuvant is the sweat cure, which strengthens the patient while reducing his obesity and leaves him with better nutrition in every respect. He reports astonishing success with the new "electric light baths," which do not raise the temperature nor accelerate the pulse, while the amount of sweat excreted is enormous. C. Schmidt has shown that the loss of an atom of alkali has a constant equivalent proportion to the albumin, so that for each single atom of alkali salts withdrawn in the respiration, nine atoms of albumin are restored to the circulation. As the perspiration lowers the amount of water and salts in the blood, angiopetal currents arise which draw the albumin out of the tissues into the blood; the nutrition of the muscular tissues is improved, while the organic albumin is protected, and fat alone consumed in the metabolism, and all the functions are more thoroughly performed. He reports hundreds of cases thus treated with a loss of forty-five pounds in weight in a few weeks, without interrupting or disturbing any functions and with increased instead of diminished energies. The process is purely physical. The aim is merely to increase the physiologic consumption of fat. The non-interference with the diet is an important advantage of this method in the frequent cases of *bons vivants*. The patient can be treated at home and the treatment resumed as necessary to maintain the benefits secured.

Washington.

HEALTH OF THE DISTRICT.—The report of health officer Woodward ended January 29, shows the total number of deaths to have been 100. Of which number 61 were white and 39 colored. Among the principal causes of death were diseases of the nervous system, 17; circulatory, 5; respiratory, 12; urinary, 7. There were 4 fatal cases of diphtheria, 1 of whooping-cough, 1 of typhoid fever and 3 of la grippe. There are 46 cases of diphtheria under treatment and 48 cases of scarlet fever.

MEDICAL ASSOCIATION.—The standing committee of the Medical Association of the District of Columbia held a meeting on the fourth instant to determine which hospitals have agreed, and which have not, to enforce the recent rules of the Association regulating the admission and treatment of patients applying for free treatment.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The two hundred and seventy-fifth meeting of the society was held at the residence of Dr. T. S. Smith, the president. Dr. W. T. Carr read the essay of the evening entitled, "Remarks on the Technique of Symphysiotomy with Report of two Cases."

Cincinnati.

THE MORTALITY REPORT for the week shows: Stillbirths 5, zymotic diseases 16, phthisis 16, other constitutional 6, local 66, developmental 12, violence, 6; total, from all causes, 122; between 1 and 5 years 18; annual rate per 1000, 15.66; preceding week, 107; corresponding week 1897, 118; 1896, 134; 1895, 115.

THE GERMAN METHODIST DEACONESS' HOME has decided to erect a general hospital.

THE CINCINNATI HOSPITAL is considering the advisability of erecting an isolation department for the care of patients suffering from infectious and contagious diseases. A bill has been drafted and will shortly be presented to the legislature asking for an appropriation of \$160,000. It is the intention to have the internes and nurses who have charge of this department also isolated from the general hospital proper.

THE NORTHEASTERN MEDICAL ASSOCIATION of Kentucky held its annual meeting in Cincinnati last week. Dr. A. S. Robertson of Sherburne was re-elected president and Dr. Adamson of Maysville secretary. Dr. C. A. L. Reed invited the association to the Cincinnati Hospital, where he performed several operations

in the amphitheater, among which might be mentioned three curettements of the uterus, one Tait's operation for lacerated perineum, one vaginal hysterectomy and one retroflexion of the uterus by abdominal section with fixation of the uterus by his own method.

HEALTH OFFICER WITHROW has presented his annual report. Dr. Withrow has inaugurated a number of innovations in the department since he entered last April. The most important being the establishment of a completely equipped chemic and bacteriologic laboratory and the anti-spitting crusade. The death rate is given as 13.7, which is the lowest ever reported for Cincinnati.

DR. EDMUND L. GROS of Paris visited Cincinnati last week en route to San Francisco. Dr. Gros was at one time assistant under Professor Charcot of Paris and he has done much original work along the line of suggestive therapeutics, scientific hypnotism and ophthalmology, his last work being a thesis on "Hydrophthalmia," which was recognized by the Faculty of Paris with a laureateship bestowed upon Dr. Gros.

SMALLPOX.—Recent reports show that smallpox continues to spread in Tennessee, and it is estimated that there are 1000 cases in Northern Georgia, Tennessee, North Carolina, Southern Kentucky and Virginia. There are several new cases in Bartow County, Ga., the total number there being fully 250. The disease has appeared at Troy, Anniston, and Hartzell, Ala., and is creating considerable alarm in mining districts of East Tennessee. Dr. Allbright of the State Health Board announced that a wholesale vaccination is the only thing that can prevent a general spread of the disease in Tennessee and in all the districts affected. Compulsory vaccination has been ordered, while places where the disease has not appeared are taking vigorous measures to prevent infection.

Louisville.

CORPSES.—At the instance of the General Baggage Agents' Association of this city, a joint meeting was held this week of the Executive Committee of the State Board of Health, the City Health Officer, a representative of the Baggage Agents' Association and a number of undertakers of the city. The object of the meeting was to consider certain recommendations of Health Officer Allen in regard to the transportation of corpses. There are a number of provisions in the laws of the various States bearing on the manner of embalming, which cause considerable annoyance to baggage agents. The agents request a perfected system of embalming by competent men, and an effort to have a uniform law adopted in order to facilitate the work of transportation of dead bodies. Rules similar to those adopted by the Illinois State Board of Health will be urged and perhaps adopted by the Kentucky State Board of Health.

EMBALMERS.—In connection with the foregoing paragraph, the Laufes House Bill, which was reported favorably by the committee on public health, was defeated by a vote of 54 to 19. This bill provides for a license for embalmers before they can practice.

DENTISTS.—House Bill 93, which was also reported favorably by the Committee on Public Health, was defeated by a vote of 43 to 27. This bill was strongly urged for passage by the State Dental Association. It provided for re-enacting the law chartering the Kentucky State Dental Association, and increased their powers in issuing licenses to practice dentistry. It also removed the headquarters from Louisville to Hopkinsville. It is to be regretted that this bill failed in its passage. This was subsequently called up by Representative Vanzant, who moved a reconsideration. The motion carried and after a long discussion the bill was finally carried by a vote of 54 to 34.

PULLIAM.—Dr. R. D. Pulliam of Leitchfield, Ky., died February 2, after an illness of less than two weeks. He was 63 years old and was one of the leading physicians of the county. He leaves a widow and eight children.

WILEY.—The Senate has confirmed the appointment of Dr. E. M. Wiley as Superintendent of the Central Kentucky Asylum for the Insane by a vote of 18 to 13. Strong opposition was brought to bear against the confirmation on purely political grounds.

OSTEOPATHY.—A bill has been introduced into the Senate by Mr. Goebel of Kenton which, if it becomes a law, will enable the State Board of Health to effectually rid the State of these quacks. It provides that "any person is prevented from practicing medicine or treating any sick person by any method whatsoever without first complying with the act of April 10, 1893, to protect citizens from empiricism."

FREE MEDICAL SCHOOL.—Among the bills advanced in the House is that one introduced by Mr. Lackey of Trigg County, providing for a State Medical College in connection with the Agricultural and Mechanical College at Lexington.

Denver.

COLORADO MEDICAL LIBRARY ASSOCIATION.—The fifth annual meeting of this association was held Jan. 17, 1898, Pres. T. H. Hawkins in the chair. Dr. Henry Sewall, the secretary, reported on the condition of the library. On Jan. 1, 1897, books, the property of the Denver Public Library, numbered 1559, and on Jan. 1, 1898, 1640; books, the property of the Colorado Medical Library Association, Jan. 1, 1897, 398; Jan. 1, 1898, 477; bound medical journals, Jan. 1, 1897, 1332; Jan. 1, 1898, 1910; Proceedings, Transactions, etc., Jan. 1, 1897, 1200; Jan. 1, 1898, 1320. It was voted to reduce the annual membership fee from \$5 to \$3. The secretary reported that some four hundred volumes of medical journals were awaiting binding, but that there was no money for that purpose. On motion of Dr. Fisk, a subscription was started to raise funds to bind these and \$120 raised among the members. Drs. Munn and Sewall were appointed a committee to solicit subscriptions to complete the amount of \$200. Officers for the ensuing year were elected as follows: President, William P. Munn; treasurer, Laura Liebhardt; secretary, Henry Sewall; librarian, John Parsons.

THE DENVER AND ARAPAHOE MEDICAL SOCIETY.—At the regular meeting of the society, January 25, Dr. Fisk brought forward a personal letter from Dr. Welch of Baltimore, asking the society to take some action upon governmental restriction of vivisection. The following resolutions were unanimously adopted:

Resolved, That it is the spirit of the medical profession of Denver that a strong protest be made against the passage of Senate Bill 1063, Calendar No. 136, entitled "A Bill for Further Prevention of Cruelty to Animals in the District of Columbia," and

Resolved, further that the president and secretary of the society be directed to communicate at once with our honorable Senators, urging them to do all in their power to defeat a bill that will do untold injury to the advancement of medical science and to the prevention of disease among mankind and animals.

Dr. Waxham read a paper, "Twenty-nine Consecutive Cases of Intubation with Twenty-seven Recoveries," and paid a tribute to the late Dr. Joseph O'Dwyer. All were treated with antitoxin. Of this number three were under 2 years of age with two recoveries, or 66 $\frac{2}{3}$ per cent. Eight were 3 years old with eight recoveries, or 100 per cent. Six were 3 years old with six recoveries, or 100 per cent. Six were four years old with five recoveries, or 83 $\frac{1}{3}$ per cent. Two were 5 years old with two recoveries, or 100 per cent., and four were 6 years old with four recoveries, or 100 per cent. Total, twenty-nine cases with twenty-seven recoveries, or 93.1 per cent. A mortality of only 6.9 per cent. This low mortality was attributed to the use of antitoxin. Dr. Levy also paid a tribute to Dr. O'Dwyer. He thought Dr. Waxham's conclusions correct. He thought that reports from those adverse to antitoxin were due to the fact that antitoxin was not administered soon enough in their cases. "Antitoxin is comparatively harmless

and it may be administered in simple anginas, and even asthma has been benefited by its administration. A diagnosis by bacteriologic examination is not necessary in every case. Here in Denver our health department has been infallible in every one of my cases." Dr. Munn thought that Dr. O'Dwyer had contributed the best pediatric idea of the century in his intubation study. He reviewed some of the statistics afforded by the city of Denver. In 1893 there were reported 178 cases of diphtheria with a mortality of 20 per cent.; nineteen of these cases were of laryngeal involvement and sixteen died. Early intubation and early antitoxin reduced this to 9 and 10 per cent. for the years 1895 and 1896. In 1895, when antitoxin was introduced into Denver, 123 cases were treated by antitoxin and 9 died, while 125 cases were treated without antitoxin and 31 died. He spoke of Dr. Crouch's diagnostic stain which contributed so much to the work of the health department. "Protest Against Dermatitis Originating from Exposure to the Roentgen Ray," was the title of Dr. G. H. Stover's paper. Dr. Rogers thought Dr. Stover was too positive in his statement that the X ray from a static machine would not burn. He reviewed the history of the girl who was burned by the X ray in New York, after an exposure of eight minutes. Dr. Freeman stated that some recent French writers had collected a record of fifty cases of injury from the X ray. Dr. Rogers also spoke of a new apparatus for localizing foreign objects in the body. The description appears in a recent number of the *British Medical Journal*.

A HOSPITAL IN BOULDER, COLO.—When the supreme court of Colorado handed down a decision last summer, denying the constitutional right of the University of Colorado to conduct a branch of the medical department in Denver, it became necessary to abandon the last two years of the medical course of the University. It was impracticable to attempt to conduct the two final years of the college without clinical work. A meeting of the citizens was held and it was decided to establish a hospital. The city council appropriated the sum of \$3000, and the board of commissioners have assured an appropriation of \$5000. It is expected that the building will be ready to receive patients by next fall.

Societies.

The following meetings are noted:

Connecticut.—Bridgeport Medical Society, February 1.

Illinois.—Kankakee County Medical Society, Kankakee, February 3.

Kansas.—Montgomery County Medical Society, Coffeyville, January 28.

Kentucky.—Floyd County Medical Society, Louisville, February 3.

Massachusetts.—Fall River Medical Society, February 2.

Michigan.—Saginaw County Medical Society, Saginaw, January 28.

Minnesota.—Minneapolis Academy of Medicine, February 2; Ramsey County Medical Society, St. Paul, January 31.

Nebraska.—York County Medical Society, York, February 1.

New York.—Niagara County Medical Society, Lockport, January 27.

Ohio.—Lucas County Medical Society, Toledo, January 28.

Pennsylvania.—Harrisburg Academy of Medicine, January 28; Oil City Medical Club, January 28; Luzerne County Medical Society, Wilkesbarre, February 2.

West Virginia.—Mason County Medical Association, Pt. Pleasant, February 1.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from February 5 to 11, 1898.

Capt. Jefferson D. Polindexter, Asst. Surgeon, will report in person to the president of the Army retiring board convened at the Army Building, New York City, at such time as he may designate, for examination by the board. By direction of the President.

Major Louis S. Tesson, Surgeon (Ft. Ethan Allen, Vt.), is granted leave of absence for six months on surgeon's certificate of disability, with permission to go beyond sea, to take effect on or about Feb. 20, 1898.

Capt. William L. Kneedler, Asst. Surgeon, is relieved from duty at San Diego Bks., Cal., and ordered to report in person to the superintendent of the U. S. Military Academy, West Point, N. Y., for duty at that post.

Capt. Charles F. Masou, Asst. Surgeon, is relieved from duty at West Point, N. Y., to take effect upon the expiration of the leave of absence granted him, and ordered to Ft. Logan, Colo.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending February 12, 1898.

P. A. Surgeon L. H. Stone, retired, February 10.

ORIGINAL ARTICLES.

REPORT AS RESIDENT PHYSICIAN OF THE ISOLATION HOSPITAL (YELLOW FEVER).

Read before the Orleans Parish Medical Society, Jan. 22, 1898.

BY HAMILTON P. JONES, M.D.

VISITING SURGEON CHARITY HOSPITAL AND ASSISTANT DEMONSTRATOR OF
CHEMISTRY MEDICAL DEPARTMENT, TULANE UNIVERSITY OF LOUISIANA,
NEW ORLEANS, LA.

The instituting of the Isolation Hospital and the choice of its site showed the wisdom of the board of administrators of the Charity Hospital and its officers, which was amply brought out by subsequent developments and results.

The site was an ideal one for the purpose, consisting of a large isolated square of ground, in a very sparsely settled district, containing main and out-buildings well grouped about its center, the nearest inhabited building being fully six hundred feet from any of the hospital buildings.

It is worthy of note that no known case of yellow fever occurred within a radius of ten squares of the hospital during the entire epidemic, and but one occurred at that distance before the establishment of the hospital.

The ambulance, although quartered at the Isolation Hospital, was under the absolute control of the Board of Health and was maintained by it, all patients being delivered to the hospital.

By far the majority of patients were brought in the ambulance, a great many in the city wagon, many, however, were brought in cabs, wagons and in the cars and some even came on foot. Those delivered by the ambulance and city wagon had always seen a reputable physician and were brought out on his diagnosis, the remainder were diagnosed before admission by me, and Dr. Veazie, if present; and accordingly were sent to the detention camp or Charity Hospital, if not suffering from yellow fever; if suffering from the disease, into the wards, or if only suspicious, were sent into a tent used for the reception of cases of that class.

I generally saw each patient and made an examination before removal from ambulance, and supervised the removal. No matter what the physical condition of the patient our invariable rule was to have them transferred from the vehicle in which they arrived, in the recumbent position, on a stretcher, to bed, without allowing them to lift a finger toward their own assistance. Too much stress can not be laid upon the importance of this procedure, and the same method should be pursued at the initial point.

The patient was conveyed directly from the ambulance to his bed and placed therein, clothes and all; he was then stripped and given suitable apparel.

The patient's personal effects, money, etc., of value

were disinfected and taken in charge by the Sisters, while the patient's clothes were washed, disinfected and placed in the fumigating room where two three-burner Truax-Greene-Hollister formaldehyde lamps were kept constantly burning.

Dr. Pothier our pathologist, at my request, placed therein air dried strips of cotton cloth which had been dipped in cultures of typhoid, Sanarelli and some germs obtained from the body of postmortem number one, of our series. These strips were subjected to the action of the formaldehyde gas for forty-eight hours; cultures under bacteriologic precautions were then made, which gave splendid growths, after expiration of thirty-six hours; the formaldehyde gas not having apparently affected the germs in the least. Investigations conducted at the Pasteur Institute and published in the *Annales* for Sept. 25, 1896, proved that formaldehyde was a good surface disinfectant for walls, etc., but had no penetrative power. I do not consider it efficient for the disinfection of clothing or anything requiring penetration.

I make these statements after mature consideration, as at an earlier period of this season I advocated its use. The formaldehyde lamps I consider especially unreliable.

The clothes were kept in these fumes until the patient's discharge. In case of death, the clothes were either destroyed by fire, or were given to some needy convalescent.

All infected linen, sheets, pillow cases, towels, etc., from the hospital were at once placed in a solution of bichlorid of mercury 1 to 1000, then boiled and washed. All urine, feces, urinals, night vessels, slop-pails and all utensils, such as sick-cups, thermometers, etc., were constantly disinfected with carbolic acid and solutions of bichlorid of mercury.

The utmost care was taken to destroy with fire all contaminating material capable of such treatment. The wards, halls, etc., were kept scrupulously clean and free from contaminating material, such as old shoes, rags, etc.

Catheters and surgical instruments were subjected to the usual process of sterilization.

In the cases of persons dying in the wards, the bodies were treated in accordance with the regulations of the Board of Health. The body was at once wrapped in a sheet wet with bichlorid of mercury 1 to 1000, after being divested of all clothing, and was then conveyed to the dead house. All burials whether by the hospital or by friends were done under the regulations of the Board of Health.

Cured patients were discharged after having their clothing and personal property thoroughly disinfected and their own persons given a thorough bath in a warm solution of bichlorid of mercury 1 to 2000, and being wiped off in pure alcohol.

Of necessity no visitors could be allowed at the hospital on their own account, as well as on that of

the inmates. Very few physicians were granted the privilege of visiting the institution, the welfare of the patients being our plea, as it is known that too much company, examination and discussion of symptoms is very injurious. Aside from Prof. E. S. Lewis, Dr. J. D. Bloom, Visiting Physician Veazie, and Pathologist O. L. Pothier, the following physicians were granted the privilege of prosecuting their studies in yellow fever in the hospital: Dr. P. E. Archinard, Bacteriologist of the Louisiana State Board of Health; Dr. Bernard Baker of Charleston, representative of the Medical Society of Charleston; Drs. Geddings and Wasden of the U. S. Marine-Hospital Service.

Composite chart of forty-five cases of yellow fever treated at the Isolation Hospital.

Dr. O. L. Pothier, Pathologist of the Isolation Hospital, especially extended to these gentlemen the facilities of his department and the deadhouse for the prosecution of their labors and the obtaining of cultures.

Dressing rooms for the visiting physicians, ministers, priests, etc., were provided in a building constructed specially for that purpose at the front of the main building. Each visitor, without exception, was required to exchange his outer clothing for a suit of white duck, previously soaked in a solution of bichlorid of mercury which was allowed to dry on it; to exchange his shoes for canvas ones and to wear a cap. At the conclusion of the visit, soap, water, tow-

els and the necessary disinfecting solutions were provided. By the indiscriminate enforcement of these regulations, the danger arising to the community, from the visits of physicians to the hospital, was reduced to a minimum.

Composite chart of six fatal cases other than yellow fever, treated at the Isolation Hospital.

The pathologic department was of the greatest value and assistance in the intelligent treatment of the cases. In every case the urine was examined microscopically and chemically for casts, albumin, etc., daily or oftener as long as indicated; no small task when the number of cases is considered.

On aduission the blood was examined for plasmo-
dia malariae and for Widal's reaction for typhoid.
The holding of postmortems was of importance
n confirming the character of the disease, aside from
familiarizing us with its pathology. The report of

ber 202 were yellow fever, with 45 deaths, giving a
mortality rate, in the hospital for yellow fever, of
22.27 per cent, exceedingly favorable when compared
with the average death rate of the Charity Hospital
for the 43 years preceding 1880 of 50.2 per cent.

Alma Brown, negro, admitted Oct. 2, 1897. Diagnosis, pelvic periton-
itis. General infection of peritoneal cavity and death. Inserted for
comparison.

Dr. Pothier will show more fully the scope and value
f the work accomplished in his department.

As will be seen by the accompanying list there
ere 216 admissions with 51 deaths from all causes,
a mortality rate of 23.66 per cent. Of this num-

John Kline, admitted Oct. 6, 1897. Yellow fever; recovery. Dura-
tion, average case. A typical case; albumin 35 per cent., moist, bile
stained casts, all varieties, and bile stained debris.

Sixty-five children under 15 years were treated, with
two deaths, 3.07 per cent.

The death rate for New Orleans from yellow fever
in 1897 was 15.67 per cent. for reported cases, and in
1878 was 16 per cent. It is reasonable to suppose

that the proportion of unreported cases was the same in each year and that the severity of individual cases was the same.

Of the fourteen cases not yellow fever, six died, giving a death rate from other causes of 42.85 per cent.

The great difference in death rates is due to the fact that Americans are better fed, are not as a class habitual wine or beer drinkers, are stronger and more enlightened.

The disease runs a more severe course among unacclimated cases as is shown by the small death rate

Guseeta Mirata, admitted Oct. 25, 1897. Yellow fever; recovery. A typical case.

The cases were distributed as follows:

United States, 104 cases, 9 deaths, 8.65 per cent. death rate.

Foreign countries, 98 cases, 36 deaths, 36.73 per cent. death rate.

Chas. Johnson, admitted Oct. 28, 1897. Yellow fever; death. Severe case in a Norwegian sailor; uremia, black vomit.

among native Louisianians, 5.26 per cent. The more enlightened Americans, as a rule, reported their cases at once, while the foreigners concealed their cases until the last moment, bringing them to us in many instances too late to benefit them by treatment. These

comparative death rates argue more plainly than words the necessity for early transportation, if moved at all, and the great danger of moving patients after the stage of calm has set in. The difference between the mortality in the Isolation Hospital and that of the Charity Hospital, for former years, is due to the careful and unremitting attention given them and to the fact that, in the Charity Hospital, those previously weakened by disease and injuries, were subjected to yellow fever when they were least able to resist

As a rule, patients were not admitted until the expiration of the second day of the disease and very frequently much later, especially the foreigners. Nearly all of the cases were of a very severe type as will be seen by the reports of the pathologic department and the clinical records.

The following facts will indicate the character of cases of yellow fever treated: Albumin was almost an invariable constituent of the urine at one time or another, ranging from a trace to 80 per cent., moist, casts, renal epithelium and debris, always bile stained, and other evidences of an acute inflammation of the kidneys were present in 125 of the recovered and in all the fatal cases. Black vomit occurred in twenty-five of the recovered and in thirty-nine of the fatal cases, complete suppression of urine occurred in four of the recovered and in thirty-three of the fatal cases.

Hugo Hughes, admitted Oct. 19, 1897. Yellow fever; recovery. Severe case, marked jaundice, albumin 75 per cent., bile stained casts; slow and intermittent pulse irregularly suspended.

it, and in consequence they died in great numbers. The wisdom of the board of administrators, if by nothing else, is amply proven by the diminished death rate of the Isolation Hospital. So far as I can judge the yellow fever of 1897 was the same in character as that of 1878; and I have no reason to believe that the death rate would not have been the same in 1897, as it was 1878, had all cases been treated in the Charity Hospital in 1897, as they were in 1878.

Composite chart of twenty five recovered cases of yellow fever treated at the Isolation Hospital.

Uremic convulsions occurred in twelve of the recovered cases and in forty of the fatal.

I do not recollect having seen bile stained casts and debris without albumin being present and in every instance of yellow fever, which came under my notice, they were so stained. In several instances the finding of casts and debris not bile stained led me to suspect that the patient was not suffering from yellow fever, but from some other disease associated with kidney trouble, and subsequent developments confirmed the suspicion. A few days ago I examined the urine of a case giving very suspicious initial symptoms of yellow fever. No albumin, but one hyaline and two granular casts were found, not bile

stained. I reported that I did not consider the case one of yellow fever, owing to this fact. The case developed into one of typhoid fever. We would expect, in very early stages of a case of yellow fever, in a person suffering from any cast producing renal trouble, to find casts not bile stained, which would, as the disease progressed, become bile stained. In any condition of the system associated with casts and bile-pigments in the urine, we would expect to find and have found the casts and the *débris* bile stained. I consider these observations of the greatest importance in the differential diagnosis of yellow fever and present this new and almost pathognomonic symptom under proper circumstances for what it is worth. The fact has been observed by Prof. Joseph Jones and others that the casts in yellow fever were bile stained; but the fact that this was of diagnostic importance has never been brought out before, so far as I know. Unfortunately I have not as yet been able to make any comparative observations on the presence or absence of the bile-pigments in the urine of dengue cases.

Hemorrhage from the bowels occurred in seven of the recovered cases and ten of the fatal; pneumonia, in one recovered case and one fatal; diarrhea in one recovered case and dysentery in two. Three recovered cases were associated with pulmonary tuberculosis.

The following complications were found in the recovered cases: paralysis two cases; delirium tremens two cases; peritonitis two cases; hysteria one case; round worms vomited by children twice.

The following is an analysis of the condition of the forty-five fatal cases on arrival: nineteen were moribund and died within a few hours of admission; thirty-three had complete suppression of urine; twenty-seven had black vomit before admission, and five, hemorrhage from the bowels.

Postmortems showed that over 40 per cent. of these cases suffered from some chronic trouble, either of kidneys, liver or heart.

These figures will explain in a measure the death rate of this institution as compared with others, and that of the city. It must also be borne in mind that every case was admitted here, no matter what the physical condition, in many instances after being refused admission elsewhere.

Bearing in mind the very important fact that yellow fever is a self-limiting disease and one that can not be arrested by drugs, our treatment was almost entirely symptomatic, each case being treated entirely on its own merits, our effort being directed rather to the prevention of bad symptoms than to their cure.

Every case should be and was regarded as serious and on account of the pathologic changes induced in the heart, liver, kidneys and other organs, etc., was given the closest medical attention, and most careful nursing. Since so many of the symptoms are due to the arrest of the functions of the skin and kidneys, efforts were directed to promote the activity of these organs during the progress of the disease, stimulating diuretics were avoided. The free use of hot mustard foot baths and hot cans, the regulating of the temperature of the room, large draughts of cream of tartar, lemonade, orange leaf tea, water, plain and carbonized, all tended to promote diuresis and diaphoresis.

Absolute rest in the recumbent position was maintained, the necessity for which was indicated by the cardiac weakness.

Pain in the head was relieved by phenacetin and the ice cap, while pain in the back and limbs was relieved by chloroform liniment, mustard plasters, etc.

Efficient but gentle purgation in the first stage was always beneficial, 0.52 or 0.65 grams of calomel followed by a dose of casto oil, Seidlitz powder or salts, usually being sufficient. It was observed that as a general rule those patients who received this treatment before admission, usually did better than those who had not. Purgatives, as a rule, were not administered during the stage of depression unless specially indicated by uremia or some such trouble, when calomel, in 0.32 or 0.65 gram doses, was generally given.

Where the stomach was overloaded with food in the early stages an emetic was administered with benefit, but it was rarely required.

Hyperpyrexia was treated by the administration of one or two doses of phenacetin, rarely more than two doses were ever given, reinforced with caffeine and brandy. The administration of hot mustard foot baths, hot drinks and the application of hot cans to the patient, by inducing free perspiration, were efficient agents frequently used for the reduction of temperature. Sponging the surface under the cover with tepid water and alcohol, Florida water or vinegar, had a soothing effect on the patient and very frequently was efficient. The injection of large quantities of ice water into the rectum not only had an exceedingly prompt effect on the temperature, as a rule, but served to flush out the kidneys and promote their functions.

Arrest of the functions of the kidneys owing to the gravity and nature of the alterations in their structure is beyond the relief of drugs. However, as the urine was always intensely acid it was our universal custom to administer an alkali in one form or another, usually a mixture of bicarbonate of soda 0.65 grams to the dose in peppermint water. This not only acted as an anti-acid but was a very valuable gastric sedative and anti-emetic.

Much good was accomplished and the functions of the kidneys restored by the injection, high into the rectum by means of the rectal tube, of a pint or more of ice water, if indicated and the patient could endure it, or high enemas of a mixture of acetate of potash grams 2, infusion of digitalis 14.8 c.c. and water to make 1 liter; these were given every three or four hours as indicated. The dose of digitalis was regulated to fill indications.

Diuretin "Nolle" was used, but so far as I observed, without success. Fluids freely were our main reliance and were given the patients on the slightest pretext.

Dry cups were frequently used over the loins and kidneys, followed by the application of sinapisms; this procedure was in many cases very effective.

Retention of urine was a very common condition and was relieved as necessary by the catheter.

A few blood cells were occasionally found in the urine and hemorrhages from the urethra occurred in two cases, but in none could the quantity of blood present in the urine account for the quantity of albumin present. All varieties of casts were found. Complete suppression of urine is an almost invariably fatal symptom, and suppression either partial or complete is the chief cause of the hemorrhages from the stomach and bowels.

The following causes also contribute toward the production of black vomit, which in itself, is salutary in effect and seems to be rather beneficial than oth-

erwise, it being an effort of nature to rid itself of retained poisons and if it were not for the grave pathologic condition with which it is associated and of which it is more a symptom, would undoubtedly prove to be the turning point in many a case of yellow fever.

The irritation of the gastro-intestinal mucous membrane, its congestion and fatty degeneration and the degeneration of the walls of the smaller blood vessels and capillaries is an identical process to that which occurs in almost all of the parenchymatous structures of the body, such as the liver, kidneys, etc. Persistent vomiting and threatened black vomit were treated very much alike. Iced drinks, such as milk, lime water, lemonade, etc., were given, large quantities of cracked ice swallowed by the patients and ice-bags applied to base of neck, throat and epigastrium; soda and peppermint were also used with advantage, and in persistent cases of vomiting or hiccough codein 0.016 to 0.032 gram hypodermatically, or cocain 0.032 to 0.65 gram by mouth, would give the patient a little much needed rest. Opiates and depressing agents were used with great caution.

During the stage of depression alcoholics were used with caution, iced champagne appearing to be the best form, but in many instances, for the control of vomiting, etc., iced seltzer water or any other carbonized drink answering just as well. During the initial stages unless specially indicated alcoholic stimulants were abstained from.

Black vomit was best treated by absolute rest of the stomach, nothing being given by the mouth, nourishment and fluids being given by rectum and medication hypodermatically.

Strychnia, digitalis, digitalin, brandy, etc., were all freely used in the treatment of the disease hypodermatically when indicated, as was atropin, in suitable doses, which was especially useful where there was a cold clammy skin or depressing perspiration associated with sub-normal temperature.

The very slow and irregular pulse of the stage of calm was aided by the above measures. So long as the pulse ran a moderately slow course all went well, as a rule, and, on the other hand, an increase in the frequency of the pulse with diminished force was generally observed near the fatal issue, with a fall in the temperature sometimes as low as 95 degrees F., when there was much free hemorrhage from the stomach or bowels. Owing to the impaired functions of the liver and intestines, the extravasated blood into the gastro-intestinal tract was very prone to putrefactive changes and was a source of much of the secondary fever. The danger arising from this source was in a measure obviated by the use of intestinal antiseptics, such as the sulpho-carbolate of soda, salol, etc.

I practiced infusion with a pint or more of hot saline solution in four cases, three of which were comatose from uremia and had had black vomit and hemorrhages from the bowels, and one of which was comatose from uremia alone and had lost no blood. This case was bled through the median cephalic vein, first to the extent of eight ounces and was then infused with twenty-four ounces of a hot saline solution. I thought that these procedures rather accelerated the fatal issue.

Hypodermoclysis was practiced in five cases, none of which recovered. About twelve ounces of properly prepared and sterilized solution was injected very

slowly into the loose cellular subcutaneous tissues of the back and sides, every eight or twelve hours. As this is a less formidable procedure I prefer it to infusion. I think that I used these agents at too late a stage of the disease, all of the cases having had convulsions and being moribund.

Delirium and uremic convulsions were treated by attending to their causes. Sedatives such as the bromids and chloral were given cautiously when indicated. Quinin was not administered unless the malarial organisms were found in the blood, which occurred in about sixteen cases. Other complications such as pneumonia, diarrhea, etc., were treated as the condition of the patient permitted, but generally as little as possible.

The diet consisted of liquid food at regular intervals during the entire course of the disease, milk and lime water, beef tea, chicken tea and the like being our main articles of diet.

But these were given at such intervals that our treatment was practically a starvation one. There was a constant cry from the patient for food. After the stage of calm was safely passed the diet was cautiously increased.

Fifty-one postmortems were made, of which forty-five were from yellow fever and six were from other causes, in every instance confirming the diagnosis made by us. In the yellow fever cases the following postmortem conditions were generally found.

The pupils were generally widely dilated and the conjunctivæ and sclera jaundiced. The skin of the face and upper portion of the trunk was generally of a golden-yellow color; while that of the dependent portions presented a mottled purple and a yellow ecchymosed appearance due to postmortem hypostasis.

On section the blood was dark and fluid, becoming bright scarlet on exposure, whilst all the tissues were found bile-stained, even the brain substance.

Intense congestion of the blood vessels of the thoracic and abdominal viscera was observed.

The pericardium was intensely congested, especially about the base of the heart, as were the capillary vessels covering the aorta and other large vessels in the neighborhood. This congestion was more marked than in any pathologic condition I have previously seen, and was not present in the six postmortems held on the cases not yellow fever.

The heart was found filled with dark fluid blood, and the muscle softer and paler than normal, due to a condition of acute fatty degeneration. The blood as has been observed by Jones and others, has its fibrin very much diminished.

The lungs presented extreme congestion of the dependent portions. Circumscribed hemorrhages ranging in size from that of a pin point to that of a pea and larger, were frequently found in all the organs.

The mucous membrane of the stomach was intensely congested, softened and eroded; often containing large quantities of black-vomit, where none had been vomited before death. This was of an alkaline reaction due to the presence of ammonia, resulting from the antemortem decomposition of urea. The presence of the ammonia according to the observations of the late Professor Jones was easily demonstrated by holding over the opened body a rod which had been moistened in hydrochloric acid forming white clouds of ammonium chlorid $\text{NH}_3 + \text{HCl} = \text{NH}_4\text{Cl}$. Microscopically the black-vomit presented blood corpuscles, gastric epithelium, bacteria, etc.

The duodenum, as a general rule, presented the above conditions intensified. This condition, however, in the majority of cases extended only down to the opening of the common bile-duct, below which the congestion was not so well marked. The intestines were dark in color and distended with gas; frequently the mucous membrane was so congested as to present the appearance of being raw. They frequently contained large quantities of black altered and decomposed blood, showing the necessity for the use of intestinal antiseptics.

The liver was generally yellow, dead-leaf or box-wood in color, due to fatty degeneration, bloodless; in deaths occurring early in the disease the liver was found to be intensely congested and yellow. Where yellow fever was engrafted upon chronic malaria the characteristic lesions of both diseases were found.

The gall bladder was generally flaccid and empty, being over-distended in only one case, where an impacted gallstone was found. The gall bladder sometimes contained a clear, albuminous, mucoid liquid, free from bile, and in some cases was filled with dark grumous blood.

The spleen was generally slightly enlarged, the parenchyma being generally normal.

The kidneys were generally of a brownish yellow color, larger and softer than normal, loaded with fat and were generally intensely congested. The capsule was generally adherent due to former troubles, while the cortex was swollen and fattily degenerated. The fatty degeneration first and generally most prominently showing itself in a line close to the bases of the Malpighian pyramids, as this sign was first noticed by our pathologist, I think it may with all propriety be safely and properly called "Pothier's sign."

The kidneys presented all the evidences of an intense acute inflammation. Putrefactive changes as a rule set in early and progressed very rapidly, associated with rapid disintegration of the blood. Blood taken from the living subject also disintegrated rapidly.

Complete clinical histories and records, pathologic reports, postmortem reports of all autopsies, accompanied by results of microscopic observations, together with the preservation of the microscopic slides and bacteriologic preparations, will constitute one of the most valuable and complete series of reported cases of yellow fever ever made.

Upon the completion of this work it will be placed in the archives of the Charity Hospital, where it will be at the disposal of the medical profession.

In conclusion I would state that no material advance has been made in the treatment of yellow fever; that the clinical and pathologic observations, microscopic and otherwise, both on the blood and tissues, of such men as the late Prof. Joseph Jones have been but confirmed.

The only really new work done was in the examination of the blood for malarial organisms. Widal's re-action for typhoid and yellow fever (*Sanarelli's bacilli*), in these cases; blood counts were also frequently conducted.

No great changes were found either in the number or structure of the corpuscles. Blood counts and examinations for the malarial organism were always made immediately after obtaining the specimens, within fifteen minutes, while the "Widal's reactions" were made when convenient. The work in this line conducted by the pathologist of the hospital, Dr. O. L.

Pothier, as yet not being in readiness to report upon. The bacteriologic work undertaken by the above mentioned gentleman, and Dr. Pothier, Dr. Mioton and myself, while not original in any but a few points, still is along a new line of intense and absorbing interest to the investigator and of vital importance to these affected by the ravages of yellow fever.

So far as I can gather from Drs. Archinard and Pothier, the two principal workers, and so far as my own observations extend the prospects for the substantiation of the claims of Sanarelli of Montevideo, are good.

The Isolation Hospital was open in all about two and a half months, closing about December 14, 1897, and during this entire time the health and spirits of the entire corps were of the best.

No case of yellow fever was traced to the hospital, in spite of the fact that three of the Sisters had not had it. The ambulance superintendent had never had it, and was frequently covered with black-vomit. Fourteen cases passed through the wards who did not have the disease, none of whom contracted it, and of the army of prisoners engaged in destroying the infected buildings and in general cleaning up, numbering in all considerably over a hundred persons, not one contracted the disease.

A TYPICAL CASE OF YELLOW FEVER ILLUSTRATING THE VALUE OF WIDAL'S REACTION WITH THE BACILLUS ICTEROIDES.

BY OTTO LERCH, A.M., M.D., PH.D.

NEW ORLEANS, LA.

Frank, age 30 years, native of England, has resided in Louisiana during the past fifteen years. He is of florid, healthy complexion, weighs 160 pounds and has been employed in a Turkish bath establishment for several months, attending in the hot room and giving massage to the frequenters of the establishment. During the recent epidemic of yellow fever he has been employed as a nurse for patients stricken by the disease. During all this time and up to the 21st he has been in perfect health. On the 22d, at 8 p.m., he was seen by the writer and gave the following history: That on the day previous he was taken with a headache and general malaise, especially soreness in the limbs not severe enough to keep him from his daily occupation in the hot-room. He thought he had no fever on that day. On the morning he went from home to his work, a distance of about fifteen blocks, and though not feeling well, worked till the time he called the writer. He was stretched upon a cot, was very restless and complained of severe pain in the head, back, epigastrium and extremities. There was nausea and congestion of capillaries, especially of face; conjunctivæ were injected; tenderness upon pressure over epigastrium; tongue coated in the center; edges and tip of tongue red. He had urinated during the day and described the urine as being scanty and of high color. His intellect was clear; a slight chill had preceded the rise of temperature to 105; pulse 113; respiration 26. A hot foot-bath and a calomel purge 0.39 gram in 0.065 gram doses every hour, followed by a saline cathartic, were administered and the following powder given twice during the night: phenacetin 0.2, codein 0.02 and caffeine 0.065 gram. The hot foot-bath, ice to the head and the above powder relieved him considerably, and on the morning of the 23d he returned to his home. At 8 a.m. his temperature was 102, pulse 80, pain over the epigastrium very severe and frequent vomiting. During the night he had taken iced seltzer water in small quantities at frequent intervals. This, however, though mixed with lime water, had not stopped the vomiting. He thought that it had lessened the nausea. The urine was scanty and contained about 3 per cent. of albumin and some casts of the uriniferous tubules. The vomit consisted almost solely of mucus tinged with bile. In the evening I found the temperature had risen to 103½, whereas the pulse had remained stationary. The vomiting had stopped, nausea lessened; he complained still of soreness, but not of pain except over the epigastrium. On the 24th, temperature 103½; pulse 80; the patient

appears and feels much better than on the previous day; evening, pulse 80; temperature $102^{\circ}\frac{1}{2}$; vomiting has stopped and he rests better. On the 25th, temperature 100; pulse 70; patient feels well, is hungry and wants to go to work; evening, temperature 101; pulse 70. After this date the patient was seen by a colleague who reported that on the 26th he found temperature and pulse normal and the patient feeling well, and he returned a few days later to his accustomed work.

On the morning of the 23d blood was taken with due antiseptic precautions from the tip of finger, and a few hours later examined under the microscope. It had almost the appearance of colored water, the red blood corpuscles being to a large extent dissolved. The Widal reaction with the bacillus *Steroides* of Sanarelli was then applied and gave the following results: In a dilution of one to ten arrest of motion of the bacilli and agglutination was complete within a few minutes, and in a dilution from one to forty the agglutination and arrest of motion of the bacilli took place within twenty minutes. The test was made with a culture obtained from Sanarelli, and the reaction was submitted to Drs. P. E. Archinard and B. S. Woodson.

The foregoing case shows several points of interest. It is a typical case, though occurring after the epidemic had subsided. From the onset of the disease we can observe the non-correlation of the lines of temperature and pulse, one of the characteristic features of yellow fever, its continuity to the fifth day with but a slight remission on the second day of the disease proves it a fever of one paroxysm, the maximum elevation of temperature is attained on the evening of the first day 105° degrees in the mouth below the tongue. On the morning of the second day the temperature registers 102° , rising in the evening to $103^{\circ}\frac{1}{2}$ degrees, and from this time shows a steady fall, all on the morning of the fifth day the temperature has reached normal. The pulse on the commencement of the attack was rapid, 113 and full, falling to 70 beats on the morning of the second day and remaining stationary the second and third days; its frequency falling to 70 on the fourth day. If we observe that on the second day a larger amount of albumin is found in the scanty urine, a symptom so constant in yellow fever that it is almost generally accepted as one of the pathognomonic features of the disease, and if we further note the congested face, pain in the epigastrium and characteristic vomit, headache and soreness in the extremities, the complete anorexia we can not doubt the diagnosis.

It seems strange that a man who has been almost daily and freely exposed to the cause of the fever during the epidemic, without being attacked, should succumb after further exposure to the cause had almost become an impossibility, the city having been practically free from the disease for several weeks. It seems that his system gradually becoming saturated with the cause of the fever had acquired a certain immunity, which it lost after a spree or some other weakening cause of which the patient does not give a history. That such an immunity can be acquired we have daily occasion to observe in this country where everybody is constantly exposed to the malarial organisms, and yet be subject to attacks of the disease only after a similar cause. More than this it is well known that men living in perfect health for years in a malarial country, suffer from malarial attacks when changing their abode to a country free from this disease, proving conclusively that they have carried the plasmodia in some form perhaps through a number of years without inconvenience. The demand made upon the system to adapt itself to new surroundings, to a new mode of life is often sufficient to cause malarial attacks.

Another point of interest in this case is, that the

occupation of the patient in the Turkish bath, where he had to be a large portion of the twenty-four hours, in the hot room with a temperature of 160° , was not sufficient to kill the bacilli, which according to Sanarelli and the recent observations of P. E. Archinard in collaboration of R. S. Woodson and J. J. Archinard, are the cause of the disease. Though the blood temperature is not raised, with each breath taken in the hot room, the heated air is brought in direct contact with the blood and the heat is immediately communicated to the tissues. If the Turkish bath can not be considered a prophylactic agent in yellow fever it may alone or in connection with the steam bath, serve as a prophylactic in other infectious diseases.

The blood, six hours after extraction presented almost the appearance of colored water.

Joseph Jones ("Treatise on Yellow Fever," p. 185) states: "The changes of the blood appear to be continuous from the time of the introduction of the poison to the fatal termination." (P. 186) "In some cases there is an almost entire disappearance of the fibrinous element," and (p. 188) "rapid dissolution of the colored corpuscles after the blood is abstracted from the body either during life or after death. The rapid alteration of the investing membrane of the colored blood corpuscles in the blood of yellow fever, after the abstraction of the blood from the vessels appears to be intimately related to, if not absolutely dependent upon, the physical and chemic action of the biliary and urinary constituents retained in the blood. During life the blood corpuscles in virtue perhaps of their vital endowments and of their relations to the oxygen received during respiration, resist the solvent action of the bile, urea and ammonia, but after the blood is abstracted and loses its vitality and is exposed in vessels these agents exert their characteristic action."

At the present day nearly all observers agree that the blood of yellow fever patients presents a normal appearance, yet others maintain that in some cases the blood shows a decided tendency to dissolution. This discrepancy of opinion may be due to the time of observation after extraction of the blood from the patient. I have no doubt that in this case the changes seen were postmortem, though I had no opportunity to verify this.

Sternberg ("Report on the Etiology and Prevention of Yellow Fever," p. 147) says that "the blood in yellow fever has been described by many observers as 'completely disorganized' as to its histologic elements. This is a mistake, as shown by the numerous micro-photographs made by the writer while at Havana in 1879, from the blood of cases near a fatal termination." The same author and others say that the prognosis in a case of yellow fever should be guarded. In the case under consideration the temperature on the first day rose to 105° , and 3 per cent. of albumin was found in the urine on the second day. Yet the case goes on without any complication to recovery within five days, and soon thereafter the man returns to his usual occupation and has been attending to it since without interruption. Quoting from the above report we find in a series of cases in which a complete and careful record had been made by G. Sternberg that when the temperature rose to 105° and 106 out of thirty-six cases, twenty-two died and when the temperature rose to 104° and 105° , out of eighty cases twenty-four died.

Though cases which appear mild at the outset may

assume a grave character we see that in this instance the reverse was the case.

The prompt agglutination of Sanarelli's bacilli and their arrest of motion in the hanging drop culture contaminated with the blood of this patient may prove of the highest value in the future and allow an early recognition of the dread disease, permitting a quarantine when it is yet of value to limit the spread of the fever.

LUPUS VULGARIS—ACUTE ECZEMA— CHRONIC ECZEMA—PSORIASIS.

A Clinical Lecture to Members of the AMERICAN MEDICAL ASSOCIATION,
delivered in the Medico-Chirurgical Hospital of Philadelphia,
June, 1897.

BY JOHN V. SHOEMAKER, M.D., LL.D.

PROFESSOR OF SKIN AND VENEREAL DISEASES IN THE MEDICO-CHIRURGICAL COLLEGE AND HOSPITAL OF PHILADELPHIA.

I have no fear of dwelling too much upon specialism because I find in numerous cases that the visible cutaneous affection is but symptomatic of some morbid functional or organic condition of the digestive organs, the blood, the kidneys, the genital apparatus or the nervous system. Consequently, in order to cure the disease of the skin I must apply the same diagnostic and therapeutic principles by which every general practitioner is guided. Dermatology is linked in the closest bonds to general medicine. This is a fact upon which I constantly insist.

LUPUS VULGARIS.

The first patient I introduce to you is a young farmer, 28 years of age, who entered this hospital a few days ago on account of an extensive and disfiguring eruption upon the face. The disease began fourteen years ago on the bridge of his nose and, as far as he can remember, in the form of scales. In the course of an indeterminate time these scales fell, there was some blood-stained fluid discharge and an indolent ulcer left. After a time larger and thicker scales formed upon this surface. The progress of the disease was attended by itching and pain. In the early course of the affection, during his boyhood, the nose was accidentally scratched by a piece of glass and this injury, he thinks, aggravated the disease, and caused it to spread with greater rapidity. Gradually the lesions extended from the nose to both cheeks and also along the nose to its tip. For the last eight years the diseased area has been of about the same dimensions as at present. The intensity, however, is not always the same. There are periods of exacerbation and improvement. The malady is generally less active in summer than in winter. There are other morbid foci upon the left cheek and chin. These began at about the same time as that upon the nose and have pursued a similar course.

At the present time the disease occupies the nose from root to tip, extending outward upon each cheek, forming some resemblance to the figure of a butterfly with outspread wings. Upon the left side a thin streak of the same character dips downward at a right angle from the tip of the wing to the corner of the mouth. Over the zygomatic process and malar bone of the right side is an oval patch of the same aspect, its long axis being in the vertical direction. Upon the right side of the chin, its center corresponding to a line dropped from the corner of the mouth, is another oval patch, the long axis of which is directed parallel to the lower border of the maxilla.

There are no other lesions upon the body than those enumerated. The patient's general health has been good until within the last few days, when he began to be troubled with pain in the lower limbs and debility. The difficulty seemed to be of a rheumatic character. Until this attack he had been able to do his farm work. He never had rheumatism before this time. The man's mother died of phthisis. He thinks that a brother also died of consumption. He does not know of any other case of skin disease in his family.

This case is of interest as regards the persistence, inveteracy, location and contour of the lesions. He has given us his history as far as he is able, but there is one important point which is omitted from his account. Upon examination I find around the borders of the lesions a number of small yellowish red papules. These vary somewhat in size, though none are large. They are moderately firm to the touch: I can distinguish that they originate in the corium.

The early period of life at which this affection began, its very chronic course, without much deterioration of general health, the intervals of improvement, and above all, the occurrence of spots of cicatrization exclude the hypothesis of epithelioma. Nor is syphilis likely to attack a country boy of 14 years. It is sadly true that children may become innocently infected if exposed to contamination and that now and then "tardy congenital syphilis," as it has been called, first manifests itself about the age of puberty. This case, however, does not correspond to the history of syphilis. A case of syphilis of fourteen years' standing would have given rise to much more extensive and destructive lesions than are here present. There would have been deeper ulceration and bone would have been involved.

The man is a sufferer from lupus vulgaris, which ordinarily commences in childhood, affects the face by preference, is characterized by spontaneous absorption of some papules or tubercles with ulceration of others and cicatrization in certain spots. Thus in a case of lupus carefully examined we may often witness the simultaneous existence of different stages. Here we may perceive stationary, or nearly stationary, papules and tubercles. Some of the lesions fade away and disappear, while others ulcerate. At the same time we may observe evidence of former ulceration in the form of scars. These peculiarities are distinctive of lupus.

Lupous ulcers are not usually very deep, but in some instances they may penetrate the subcutaneous tissue and even involve the bone, proving as malignant as carcinoma. In other cases, an old lupus has undergone transformation into carcinoma.

The edges of lupous ulcers are soft, the surface is red, smooth, and early bleeds. It often becomes covered with thin scales or crusts. The ulceration is at times attended or followed by abundant papillary outgrowths, this form being known as lupus verrucosus. The disease occasionally begins upon a mucous membrane.

The butterfly or saddle-back contour is much more frequent in lupus erythematosus than in lupus vulgaris, though I frequently observe it in the latter affection. The course of lupus erythematosus, however, is not evidenced by papules, tubercles and ulcers, and it is commonly surrounded by comedones and patulous sebaceous ducts. Erythematous lupus develops later in life than lupus vulgaris.

There has been much discussion of late years concerning the tuberculous origin of lupus. The prevalent opinion ascribes its causation to the bacillus tuberculosis; yet these are confessedly present in small numbers and I have often searched for them in vain. It is true that lupus occurs in a certain proportion of patients affected by pulmonary tuberculosis in those who, like the present individual, belong to tuberculous families or in persons who become subsequently attacked by consumption of the lungs. Such cases, however, are greatly in the minority. On the other hand, lupus does not resemble clinically other undoubted forms of tuberculosis of the skin, and most patients afflicted with lupus possess fair general health.

The successful treatment of lupus is not an easy task. It usually demands the utmost patience in both the subject and the physician. The hygienic surroundings should be of the best and we should aim to correct any constitutional disorder which may be present. I am no advocate of severe local methods as I have frequently seen them followed by aggravation of the malady. Scarification, cauterization and curettement are procedures which I have almost entirely abandoned. I much prefer to begin with milder applications combined with appropriate regimen and internal remedies. If these prove without avail we may then cautiously resort to more heroic measures. In this case I have ordered that the diseased surface be painted every third day with pure carbolic acid. This substance has the valuable properties of coagulating the albumin of the parts, sealing up the blood and absorbent vessels and stimulating repair. In addition to these applications the following ointment shall be kept constantly applied:

R. Hydrargyri chloridi mitis	gr. xv	97
Creosoti	℥x	62
Bismuthi subnitrat.	ʒj	39
Unguenti zinci oxidi benzoati	ʒj	31
M. fiat unguentum.		

On account of the family history of the man he shall be placed upon an alterative course, consisting of 1 drachm (3.7 c.c.), gradually increasing to 2 drachms (7.4 c.c.) of syrup of the iodid of iron thrice daily, together with an equal quantity of cod liver oil.

ACUTE ECZEMA.

This man of 25 years of age, has been troubled for a week by a very extensive eruption. Commencing on the scalp it has spread to the face, neck, trunk and extremities until at the present time there is scarcely a portion of the body entirely free from the disease. The exanthem is attended by excessive itching, burning and smarting. The general health is said to be unaffected. The bowels are constipated. His appetite has not been at all impaired.

The rash exhibits different types upon different parts of the body. Primarily it consists of small vesicles, filled with a pearly white fluid and situated upon an erythematous base. After a day or two they rupture and discharge their contents, which dry into yellowish crusts of greater or less size and thickness, according to the number of vesicles which have aggregated before rupture. Upon the back of the neck the crusts are particularly large, thick and numerous.

This can be nothing else than acute eczema of the vesicular type. Of this phase of the malady it is, indeed, an apt example. Closely grouped small vesicles on an erythematous base with heat, swelling, burning, tingling and itching signify eczema. The

erythema, heat and swelling might be suggestive of dermatitis, but we have here no history of direct injury to the skin. Dermatitis herpetiformis is rare; the patches of erythema are of a dark red or purplish color, and vesicles vary greatly in size, while bullæ and pustules are often present. Herpetic vesicles do not rupture. Those of herpes zoster follow the course of a nerve and are often accompanied by sharp pain. In pemphigus we observe large bullæ or blebs.

Though vesiculation is the prominent characteristic of one variety of eczema, yet many cases run their course almost or quite free from this manifestation and require to be classed as erythematous, papular or pustular eczema according to their predominating lesions.

Acute vesicular eczema may be accompanied by constitutional symptoms so severe as to cause us to suspect the development of some eruptive fever. Such symptoms have been absent in this case notwithstanding the extensive surface involved. There have been no chills, fever, headache, backache, anorexia or nausea. The tongue is coated however, and the bowels constipated. As there has been no source of external irritation the disease in this instance is, in all probability, to be ascribed to imperfect digestion. This is a very common cause of eczema especially when, as often happens, the patient has a susceptible skin. Certain persons are predisposed to eczema as others to catarrh of mucous membranes; eczema has been termed catarrh of the skin, as affecting chiefly the mucous layer. Gastro-intestinal catarrh may be reflected upon the skin as acute or chronic eczema.

In treating such a case as this, therefore, it is important to avail ourselves first of the eliminative function of the bowel by administering a brisk purge. This should be followed by remedies which will improve the morbid condition of the alimentary tract and strengthen the digestive power.

Coincidentally with such internal treatment we should combine emollient applications to the skin. Stimulating substances are inappropriate for topical use in acute eczema. They serve only to aggravate the disorder. We should choose the milder preparations, as those of lead, zinc, bismuth, magnesium, boric acid, diluted carbolic acid, a bland oil, etc. Remedies of this kind may be applied in the form of lotions, ointments or dusting powders according to the circumstances of the case. When the initial severity of the disease has subsided, if it shows, as it often does, a tendency to linger in a subacute or chronic form, we may begin cautiously to increase the strength of our applications or adopt others of a more decidedly stimulating character.

To revert to the patient I shall begin the treatment by the administration of:

R. Antim. et potass. tartratis	gr. ss	032
Massæ hydrargyri	gr. x	65
Pulv. jalapæ	gr. x	65
Pulv. cinnamomi	gr. j	065
M. ft. chart.		

This combination will have a beneficial influence upon the secretions of the alimentary tract in addition to unloading the bowels. After he has been freely purged he shall be placed upon:

R. Acidi hydrochlorici diluti	ʒv	1848
Pepsini pur	ʒij	117
Glycerini	fʒj	2957
Aquæ	q.s. ad ʒiv	11828
M. ft. sol. Sig. Teaspoonful in water after each meal.		

If the bowels should show any tendency to become

constipated again the patient shall be given every night or two a capsule containing 1 grain (0.065 gram) each of blue mass, powdered jalap and compound extract of colocynth together with 1-20 minim (0.003 c.c.) of oil of peppermint.

On account of the almost universal distribution of the eruption the patient shall be given a moderately warm bath every day while the inflammatory action is severe. This soothes the skin, washes away the products of disease, and allays the itching. Rain water is beneficial, but the addition of an alkali and emollient enhances its efficacy. About 4 ounces of sodium bicarbonate or borate and 3 pounds of starch added to the water makes as a rule, a soothing, grateful bath in such an extensive violent case as the present. It must be admitted, however, that there are cases which receive no benefit from general baths. Injudiciously or immoderately practiced immersion may aggravate the disease. We must be guided in each individual case by the effects.

After the bath the surface is gently mopped dry when it may be anointed with a mild preparation, such as the following:

R. Calaminæ	5j	39
Bismuthi subnitratis	5ij	78
Unguenti cucurbitæ		
Unguenti aquæ rosæ	āā	3ss 156

Finally over the ointment a bland dusting powder, such as starch, arrow-root, lycopodium, talc or magnesium carbonate may be freely sprinkled. When so much of the surface is involved an ointment is usually preferable in practice to a lotion. Except in the extremest cases a patient can scarcely be expected to sit at home in light undress and continually mop the surface with a wash.

CHRONIC ECZEMA.

Some of the results of a continuance of eczema are illustrated in our next patient, a man of 40, who has been afflicted with the disease for fourteen months. The predominant lesions are of the class known as secondary. Upon the flexor surfaces of both forearms, in the popliteal region of each side, the outer surface of each leg and around the ankles as well as upon the buttocks are spots and patches of infiltration, varying in size, those upon the forearms and legs being quite large. The skin is thickened, rough, hard, dry and inelastic. It is a deep red color in these situations. The eruption is accompanied by persistent itching. The larger patches are more or less plentifully covered with thin, grayish scales. Tormented by the itching the man has in numerous places torn the skin with his nails and blood crusts have been the result. At other sites the inelastic integument has given way to muscular traction forming painful fissures. Some of these are deep and bleed easily. To the troublesome itching the fissures add an element of actual pain. The totality constitutes to the patient a very distressing case.

The eczema in this instance, is certainly due to digestive derangement. The man has marked symptoms of gastric and intestinal dyspepsia with torpidity of liver and lack of assimilation. There is much flatulence, a coated tongue with fetid breath and irregular action of the bowels. In brief there is present a condition of auto-infection by imperfectly elaborated alimentary material. It will be necessary to unload his intestinal canal, stimulate the digestive functions and regulate his diet. He shall be allowed a sufficiency of nitrogenous food of the most digestible kinds,

such as eggs, roast beef or mutton and plenty of milk with once a day some well cooked vegetables. Without attention by proper diet and remedies we should seek in vain to cure this case by means of external remedies.

I shall order first the capsule of which I have already spoken.

R	Massæ hydrargyri.	
	Pulveris jalapæ.	
	Extract. colocynthidis comp	āā gr. j 065
	Ol. menth. pip.	m. 120 003
	M. et ft. capsula No. j. Mitte tales No. xx.	

Sig.—One capsule to be taken every night at bedtime.

In order to improve his digestion he shall be given a mixture of hydrochloric acid and pepsin, composed as follows:

R	Pepsinæ glycerini	3j	312
	Acidi hydrochlorici dil.	m. ccccc	308

M. Sig.—Two teaspoonfuls after each meal.

Locally there shall be applied:

R	Acidi salicylici	gr. xv	97
	Acidi carbolic.	m. x	62
	Sulphuris sublimati	5 ss	195
	Unguenti zinci oxidi benzoati	3 j	312

M. ft. ungt.

PSORIASIS.

We have also two patients to form a contrast to chronic eczema, and which require one to enumerate the points of differential diagnosis. The first of these cases, a lad of 18, has been subject for four years to an eruption upon the scalp, face, back and limbs. Upon the hairless parts the characteristics of the lesions can be readily discerned. These consist of patches covered with silvery scales. The disease began as small, dry papules, which by their growth and coalescence became patches surmounted by the scales described. Some of these primary lesions are to be observed now upon the forearms. The patient himself points out small, discrete papules, which experience has taught him to recognize at the earliest manifestation of the disease. They are of rather a bright hue. The disease began upon the scalp. The boy first noticed an unwonted dryness of the scalp. After a time he could feel pimples upon the head, and in the course of a year scales were observed. Subsequently the eruption developed upon the side of the trunk, knees and limbs. Individual papules are at first always separated by a space of intervening healthy skin. A little scaling is seen upon their tops almost from the very first.

Large patches exist upon the breast, back, thighs, legs and arms. They are prominent upon the back of the elbows and just below the knees. The patches are largest upon the thighs and abdomen. They are thickened, red and scaly. Primary lesions are now in process of evolution upon the hands. Until recently they had never appeared in this situation.

There is not much itching. If he becomes overheated the papules and patches may itch. At such times he is apt to tear off scales in scratching, and then there is a little bleeding.

There is a distinct rheumatic history in this case. A year ago the youth suffered severely from rheumatic pains, and has ever since been subject to sharp twinges in the shoulders, loins, arms and legs. The pains are particularly sharp prior to the development of fresh lesions. He has also some dyspeptic symptoms.

The next patient is a man, 37 years of age, who for two years has been troubled by a rash presenting the same aspect as that of the preceding case. In this patient the disease began behind the elbows, and scaly patches are scattered upon various parts of the body. There is no occasion to describe them in detail. In

this individual also, there is clinical evidence of the rheumatic dyscrasia. He describes himself as constantly feeling weary, having a weak back, desiring to lie abed in the morning. He formerly possessed average energy, and is not willing to be accused merely of laziness. Nor do I regard his symptoms as due to laziness, but as the sluggishness denotive of the hepatic torpor so frequently the concomitant or the origin of subacute rheumatic manifestations.

Both these cases are stamped with the same seal. The impress is characteristic and almost pathognomonic of psoriasis. When once known this disease can generally be recognized with ease and certainty. We can scarcely mistake as regards psoriasis, but chronic cases of eczema, attended by desquamation, may bear a certain resemblance to it and engender doubt. The course of the latter affection, however, is altogether different from that of eczema. In psoriasis we have a history of individual scaling papules separated by sound skin and in almost any case the physician may himself demonstrate the existence of such primary lesions in addition to the scale-covered patches. The papules are present in both cases. In papular eczema there is no such isolation of the lesions, which moreover very frequently arise from a reddened base. Eczema has a predilection for the flexures of joints; psoriasis usually begins on parts where the epidermis is thickest. The scales of eczema are thin and scanty; those of psoriasis are thick, firm and generally of silvery aspect.

Psoriasis is fundamentally a hypertrophic disease, attended by inflammatory changes, enlargement of the papillæ of the skin and hyperplasia of the cells of the stratum mucosum. The patches in some cases assume huge dimensions, and in other instances very fantastic outlines. It is essentially a stubborn affection. The treatment and prognosis of each case depends upon its cause. The origin may be in morbid conditions of the blood, nervous system and viscera. In a large proportion of cases it is due, as in the cases before you, to the influence of rheumatism. Gout also plays a large part in its production. It follows, therefore, that successful treatment depends upon the general principles of internal medicine, and that local therapy must in many instances be of minor importance. Topical measures alone will seldom cure the malady. Quite often I order no local applications whatever, and depend entirely upon systemic medication. This is the course which I shall pursue in the case of the second patient, the older man. I shall prescribe:

R Sulphuri sublimati gr. iv 26
Potassii bitartratis gr. j 665
M. et ft. capsula No. j. Mitte tales No. xxx.
Sig.—From four to six capsules to be taken *per diem*.

Small doses of sulphur are of decided value in subacute rheumatism. In these quantities it acts by absorption, stimulates the liver, the glands of the bowel and of the skin. As a normal constituent of albumin and of taurocholic acid the administration of sulphur is a logical procedure in disorder of the hepatic and cutaneous secretions and in perverted nutrition of the epithelial elements of the skin, the cuticle, hair and nails. Furthermore, sulphur is extremely beneficial in subacute muscular rheumatism of the type exhibited by the patient.

In the case of the lad we find a more active manifestation of rheumatism. The potassium iodid will here exert a more speedy effect. I shall direct him to have 10 grains (0.65 c.c.) of that salt four times daily,

increasing to 15 (0.97 c.c.) and then to 20 grains (1.3 c.c.) according to the manner in which it is tolerated. It shall be given in the compound syrup of sarsaparilla as a suitable adjuvant. For the youth I will order the following external application:

R Unguenti hydrargyri nitratis 5 ss 195
Acidi salicylici 5 ss 195
Unguenti zinci oxidi benzoati 3 j 312
M. ft. unguent.

In such cases frequent steam baths are useful. Many practitioners accord a high value to chrysarobin as a topical remedy in psoriasis. I do not often employ this agent for the reasons already intimated. Moreover it is very irritant, and it stains the skin, hair, nails and underwear.

THE SCHOOL TRAINING OF YOUTH.

Presented to the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY CHARLES E. WINSLOW, M.D.

LOS ANGELES, CAL.

The two essential parts of a human being are mind and body, and so constituted are they that each is of the utmost importance to the other. They are bound together by ties that render them inseparable through life. A suffering body depresses the mind; a harassed mind wearies the body. That which strengthens the human organism, stimulates the intellect to action. Raptures of the mind thrill the body. This being true, how important that from the first days of life, the intellectual and physical should grow and develop side by side.

That laws of health obeyed increase and add pleasure to life, should be known by every man, woman and child in our land. Health with a fair mind is worth more than a brilliant intellect in a feeble constitution.

The broadening light of knowledge reveals truths in cause and effect of hygienic principles before unknown. These bear added responsibilities, opening up a field of labor prepared for the growth of wise thought and action. We are realizing more and more the need of staunch and energetic men who can stand against the push and energy of the day, assert and maintain their beliefs and not break down in health as they are ready to grasp the great promises of the future.

A community's healthfulness greatly aids the progress of business. The commercial interests of the nation demand the improvement and protection of human life. To promote the future prosperity of our nation, and to elevate the physical standard of the human race, we must build up the bone and sinew of the country; therefore the science of hygiene must be understood. The grandest results will be attained only when the people come to a full comprehension of the value of the laws of health. To bring the greatest influence to bear upon the education of the masses, we must begin at the foundation and enlighten the people through the growing youth of the land. We must instil into their minds a knowledge of the fundamental truths of hygiene, and increase the powers of the intellect and body, thus making a better and stronger race of men and women.

The future history of our nation will be made by the children of the present. What we do for the child of today is something done for the adult of tomorrow. Every healthy child indicates a healthy

man or woman. Over twenty-five millions of youth in the United States—what a leverage for good! These minds filled with right ideas in regard to health, would be an unmeasured power whose expanding influence would be felt in ages to come.

Our schools are the corner stone of the nation; to them with their four hundred thousand teachers must we look for the forces that are to save the strength of its people. There should the pupils be taught the laws of health by word and deed. The members of the school board should be men of intelligence, interested in the children's welfare and impressed with the fact that the lives and health of fourteen millions of school children are of vital importance to the nation. The selection of sites, building and furnishing of school houses and engaging of teachers should not be controlled by money consideration.

The rights of our school children should be recognized in all ways that will protect and develop the mental, moral and physical health. The playgrounds should be large and free from dampness; the buildings should be examples of scientific sanitation; the rooms warm and comfortable, light and airy, free from draughts and poisonous gases, furnishing two hundred cubic feet of pure air to each pupil, and everything should be clean and sweet. The walls of the room should be slightly tinted blue or green that they may be restful to the eye, and there should be the best of blackboards. Care should be taken to have desks so made and placed that they will tend to straighten, instead of deforming the child. The microbe-breeding slate should be discarded and paper especially prepared used in its place. The pencils should be disinfected daily. The school books made of suitable paper, with the printing plain and legible, should be owned and furnished by the district, thus preventing the carrying of books back and forth from families infected with disease, and also the sale of second-hand school books, coming, as they often do, from houses where disease has run riot. The use should be forbidden of the open bucket, in which, through the medium of the drinking cup, the water becomes contaminated with spittle from the mouths of disease infected children. There should be provided a place where the clothing can be warmed and dried. Children from homes saturated with germs of disease should not be allowed to endanger the lives of those from homes clean and pure.

A competent expert in the science of hygiene should carefully inspect the school and its surroundings, and thoroughly disinfect the building and its contents periodically. He should examine teachers, pupils and employes for contagious diseases, test the eyes of the pupils, see that all members of the school have been properly vaccinated, examine into suspected cases of sickness and infectious disease in families whose children attend the school. He should advise with regard to the amount of work pupils are physically able to undertake and also the kind of exercise needed by different children. He should report any needed changes in the buildings, and should lecture to the teachers and older scholars on the principles of hygiene.

The educators of our youth should be selected with the greatest care, for upon them rests a great responsibility; they are at the head of the institutions that indicate a nation's civilization; they are the developers of our citizens. Teachers are born, not made. They should have sound minds and bodies, should love

their work and be in sympathetic touch with their pupils, studying their nature. They should have a facility to impart knowledge and at all times bear in mind that there is to be a moral as well as mental and physical growth. They should wisely encourage and interest the child in the lessons to be learned, teaching him to observe and think for himself, remembering that education is in a great measure the development of the faculties rather than the imparting of knowledge. They should teach the importance of self-control, and should be able to infuse joy and gladness into the heart of the child. They should understand physiology and hygiene and learn that there are conditions of the nervous system that must be wisely handled, that there are functions of girlhood that can not be ignored, remembering that the excitement of school life often hides from the teachers the pupil's weakness. The teacher should so instil the distinction between right and wrong into the mind of the youth that there will crystallize into the life all that is best of the moral, intellectual and physical world.

Education is development of power and a storing up of that which will give strength of character, penetration of mind and endurance of body. Childhood is the molding time of life, where weakness of intellect and organism is to be overcome; when deformities of mind and body are to be corrected.

The science that aims to give better health, longer life and greater happiness to man should be paramount to all others; it is of vastly more importance to the youth to know what will prevent misery now, than to know that centuries ago Alexander sorrowed because there were no more worlds to conquer.

Make the study attractive to the student, stimulating the mind to further investigation. No child is too young to learn. Sow the seeds in the kindergarten. Let the truths be gathered all along the pathway of knowledge. Teach the children that cleanliness means health and strength. Teach them that filth and dirt infect the air we breathe, the food we eat and the water we drink, and that it breeds pestilence and transmits disease. Children should be taught not only the truths of the science of hygiene, but also the practical use of the knowledge obtained. The mind and the body should be trained to perform all their functions and live as nature intended.

No false ideas of modesty should prevent the teaching of the evil effects of youthful vices, and the danger of bringing wretched manhood and misery to those who sin through ignorance. These things would better be learned in school from wise teachers than in the street from evil-minded youths.

The older young woman should be taught the importance of motherhood and all it implies. The appalling darkness that surrounds this subject and the ignorance shown by most young women at this period of their lives is an outrage against humanity.

At no time of life is the mental, moral and physical growth so rapid as in childhood. During that period most children are in school.

The first consideration of the teacher should be "how to keep the growing child well," aiming to improve the moral and physical, as well as the mental condition.

The high pressure system of education with its daily grind of study, followed by the severe strain of examinations, exhausts the mind, causes loss of appetite, interferes with sleep, making the child listless, and is responsible for a large share of the increasing

nervous troubles. There are children who will bear crowding, but the majority, with their soft pliant brains, will not stand the strain. The per cent. of myopic cases increase as the pupils advance from grade to grade. This is due largely to close application with poor light, bad printing and defective blackboards.

Forming bones, growing muscles, developing nervous system and the constantly changing conditions of childhood need exercise.

Mind and body should be systematically trained, together growing in strength and power. Forcing either at the expense of the other is dangerous. To cram the brain of a poor, sickly body, without the vital force to use the knowledge, is to make an unbalanced human being. Cultivate good, active minds supported by the brawn and sinew of sound bodies, and they will wield an influence on this swiftly moving civilization.

Muscular tissue will not improve without muscular action. Exercise develops and tones up muscle and nerve force, thus increasing the heart's action, causing the lungs to expand and send richer blood to the brain, which brings clearness of thought and a more practical turn of mind. Manual labor and exercise should be wisely interspersed with study. Physical culture will give to our boys and girls more grace and finer physiques; the shuffling walk will be less often seen, the bent bodies will become more erect and awkwardness will disappear. Special exercises should be given to strengthen the weakest parts, fun and recreation forming part of the exercise. Motion is often rest to a child. Dr. Wey found that twelve of the duller boys in school, after a course of physical training, without their knowing why it was done, increased their rank in their classes from 45 to 74 per cent.; their minds becoming more active, facial expression more intellectual and eyes brighter.

The children of civilized nations spend too much time in-doors. Long school hours should be avoided. Make the hours of study accord with the age of the pupil, who should rest each half hour. The French primary schools with their three grades, the first of three and a half hours, the second of four and one-half hours, and the third of five and one-half hours for mental work and two hours for bodily exercise, have improved the mental and physical condition of their pupils. In the half time schools of England, the children working half a day with three hours of study, pass the fourth grade in nine and one-half years, while the full time children studying six hours a day do not show the same aptness, and are ten and one-half years accomplishing the same result.

The studies should be made interesting, cheerfulness being encouraged. Forced stillness in a school room is painful. It shows too rigid a discipline, is wearing on the pupil and tends to suppression of the spirits that are needed to make a boy or girl an energetic man or woman.

All children have not equal ability to gain knowledge, and different organisms will not endure the same amount of work.

Rigid rules can not be enforced with safety; growing youth has peculiarities that can not be bound by human laws. The calls of nature must be attended to; because children make it a pretext to go out of doors, teachers are not relieved from the criminal responsibility for the destroyed health of a child. The strain that comes to the young girl rapidly devel-

oping into womanhood is enormous, and a wise judgment should be used in meeting the dangers to her moral, mental and physical life.

The brightest pupils in school do not always achieve the grandest success in life. Machine work will not make capable men and women; the practical should be woven into the web and woof of children's lives, and their reasoning powers developed. Thoughtful meditation is worth more than impulsiveness.

Crowded education without due regard to the laws of health is responsible for the alarmingly increasing defects of childhood. The tendency to heredity, defective eyesight and hearing, pulmonary troubles and deformities, disordered digestion and shattered nervous systems threatens us as a nation.

Education should so improve the mental and physical condition of the child, that he will rise superior to his inherited tendencies; then will each successive generation grow stronger morally, mentally and physically.

In this age of excessive activity with its wonderful progress in trade, art and science, taxing brains to their uttermost, comes weariness and failure before life's work is fully completed. Education calls for the deepest search for treasures of science, which will bring to the surface grand results in a moral, intellectual and physical manhood, better prepared for life's work, thus enabling him to grasp great possibilities, and make them subservient to his will.

Civilization's light has lessened the shadows of ignorance and we begin to realize that influences are being generated now that will tend toward good or evil in the ages to come. Increased knowledge shows us the way to improve our schools, tells us what is needed to better protect and make sound in mind and body our youth, but back of this must be a power to make and enforce laws of health.

State and government must be the power, with agents systematically carrying on the work, and controlled and guided by a secretary of health at Washington.

Here on the edge of the century let us make ready for the future and send the rays of a brighter civilization into the next, by an army of perfected men and women whose exalted characters, brilliancy of intellect and physical power, will make our nation the peer of all others.

Bradbury Building.

SPASMODIC CLOSURE OF THE GLOTTIS IN THE ADULT.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY HAMILTON STILLSON, M.D.

SEATTLE, WASH.

Spasmodic occlusion of the larynx in the adult is usually of the nature of a reflex and is but a symptom of a nerve lesion more remote. The remote causes are usually those that produce paralysis of the abductor muscles, notably, the lateral crico-arytenoids and those that produce spasm of the adductor muscles, notably the inter-arytenoids. A differentiation of these causes will be essential to the proper treatment of the cases when presenting.

In the remote causes proper has been enumerated spasm of the adductor muscles. This spasm is usually found in such nervous diseases as chorea and hysteria.

The spasm may always be relieved by temporary anesthesia. It is usually not severe nor of long duration. As a rule it is relieved before loss of consciousness supervenes, the exhaustion caused by the spasm relaxing the spasm. It is of the nature of a nervous cough and is to be treated as such.

It is with closure of the glottis by paralysis of the abductors that this paper has principally to deal. There are two forms, one seen in such diseases as epilepsy, and the other in such diseases as ataxia. In the so-called laryngeal vertigo, laryngeal epilepsy, there seems to be no paralysis of the abductors except during the dyspnea. These attacks are sudden and transient. There is nearly always previous discharge of frothy mucus without premonition as is usual in ordinary epilepsy. The patient will be seized with a sudden violent coughing that amounts to strangling. He will grasp a chair or like object if convenient, and in a few seconds fall, usually upon the back, and entirely lose consciousness. The attack will last but a few seconds. The patient will regain his feet and feel perfectly well, no pain or unpleasant feeling of any kind being present. Indeed, the patient may express the idea that the remembrance of the attack is pleasurable rather than otherwise. The loss of consciousness seems to resemble that of carbonic anesthesia from nitrous oxid, etc.

About thirty cases of this form of closure of the glottis have been reported in literature with sufficient care to warrant proper classification. They are as follows: Charcot (*Comptes-rendus de la Société de Biologie*, p. 336, Paris, 1876; *Le Progrès Méd.*, 1879, xvii, p. 317), Gasquet (*Practitioner*, August, 1819), Krishaber (*Ann. des Mal. de l'Oreille et du Larynx*, 1882, p. 182), Grey (*Amer. Jour. Neurol. and Psych.*, November, 1882), Lefferts (*Arch. Laryngology*, vol. iii, p. 165, New York, 1883), McBride (*Edinburgh Med. Jour.*, March 1884), Russell (*Birmingham Med. Review*, August, 1884), Massei (*Giorn. Internat. delle Sci. Med.*, anno vi), Hermes (*Journ. de Méd. de Paris*, 1887, p. 936), Knight (*Transactions Amer. Laryng. Asso.*, 1886, p. 34), Gleitsmann (*Med. Monatschr.*, i, p. 510), Dauvin (*Journ. de Méd. de Paris*, Aug. 17, 1887), Lennox Browne ("Diseases of Nose and Throat," 3d ed., p. 526), Armstrong (*Med. News*, June 8, 1889), Adler (*New York Med. Jour.*, Jan. 30, 1892, p. 128), Weill (*La Provence Médicale*, Dec. 3, 1887), Fereol (*Progrès Médicale*, 1879, No. 17, p. 319), Phillips (*Med. News*, Philadelphia, March 19, 1892).

Much discord exists as to the nature of this form of laryngeal spasm, but in the opinion of the writer the affection is of the nature of petit mal. Regular paralysis of the abductors is more common in such affections as ataxia, and the attacks differ from those of laryngeal vertigo in that the patient, though he may fall, does not lose consciousness. They differ also in being less sudden and less transient, having less frothy mucus exuded, having often more premonitory symptoms; but the main and principal difference is that there is paralysis or paresis of the abductors at other times than in the periods of dyspnea. There is, indeed, paresis of a greater or less degree almost constantly.

In the case that I record at the end of this paper, the first attack was characterized by loss of consciousness, but in all subsequent attacks, occurring throughout several years, the patient though greatly distressed knew perfectly well all that transpired. He was

indeed, more fully cognizant of the condition of affairs than was consistent with comfort.

This form of closure of the glottis is to be carefully studied, since it is often the one observable precursor of ataxia and may appear long before any other symptoms of that dreadful disease make their appearance. Charcot, I believe was the first to mention it, though Fereol was the first to describe it fully and to trace its relation to ataxia. He gave it a most interesting and graphic description. Kussmaul and others have further developed the subject. Their researches show that when laryngeal paralysis is of central origin, it is most frequently found accompanying disease of the medulla oblongata and of the pons, as in bulbar paralysis, in multiple or disseminated cerebro-spinal sclerosis, in locomotor ataxia and in the general paralysis of the insane. In the case whose history I give below the disease occurred in locomotor ataxia of rheumatic origin.

Case.—On Jan. 5, 1894, F. M., English, aged about 35 years (occupation, proprietor of a logging camp) was brought to my office. He was of large, robust habit, florid complexion; had been drinking, and I thought at first that he was tipsy. He was led staggering and strangling into the office, his eyes staring, face livid and cyanotic, tongue out, presenting a most distressing and anxious appearance. I gave him a few whiffs of chloroform and sprayed his throat with cocaine, and got a good view of the larynx. Vocal cords highly hyperemic, as was the mucous membrane throughout the nose and throat. At rest, the vocal cords were almost parallel and tolerably close together—voice not impaired. In inspiration the vocal cords pitched down, valve-like. Later there was audible inspiratory sound, especially in an inspiration taken after the pronunciation of a somewhat lengthened sentence. In expiration the vocal cords were close together and the false cords approached. There was hypertrophy of the lingual tonsil, thickening in the region of the pharyngeal tonsil, hypertrophied follicles on the posterior wall of the pharynx, edema and elongation of the uvula, edema of the right septum posteriorly, deviation of the right and left septum and septal spurs, hypertrophy of mucous membrane on the right and left lower turbinates. Among his general symptoms were constipation and hemorrhoids. His gait was unsteady, his feet being placed wide apart. He reeled while standing with his eyes closed. There was cutaneous anesthesia on the sides of the chest and on the lower extremities. The skin was not sensitive to the pain of pricking, but very sensitive to that of heat and cold. Patient complained that cold was painful to him. Knee jerk was absent: tendon reflex was absent.

Vision, right and left, 15_{20} , unimproved; requires a +4 D. to enable him to read Jaeger No. 1 at fourteen inches. The range of accommodation was two inches. There was exophoria for a distance of two and one half degrees when looking straight forward, greater when looking to either side, diplopia when looking to the right or left of center, at which time patient complains of being dizzy.

History.—Twelve or fifteen years ago had a severe attack of rheumatism through shoulders and chest, dull soreness through muscles of chest and shoulders and for years after could not comb his hair with comfort, could not get arm up, the touch of the clothes was painful, rheumatism confined principally to the chest.

About five years ago, while engaged in the lumber business he had attacks of dizziness, especially after lifting or stooping, head would get dizzy and glimmer; had sick headache and dyspepsia, thought it was biliousness; knees would get weak and painful, especially after walking skids very much; would have sick headache every week and would end in emesis. Has not had this bilious sick headache for two years, but occasionally vomits after coughing awhile.

Four or five years ago the skin became numb: "If you would pinch it it would not hurt." It was then all around the chest. It is so now. The skin is very sensitive to heat or cold, can not take a cold water bath.

About five years ago the strangling cough attacked him. The spasm would last fifteen or twenty minutes. There would be a tickling in the throat as though a bread crumb were there, would hawk and try to get it out, then would cough and strangle, did not lose consciousness in these attacks nor fall, neither was there much expectation. What he did spit up was a sort of white foamy phlegm. At first the attacks would

last from ten to fifteen minutes, "seemed to be caused by the drawing of the breath." Sometimes the patient would hold his breath to keep from having the pains.

A year or two ago had twitching of the eyelids on the right side. At that time the numb skin on the trunk felt creepy, especially when the clothes would touch it, and the patient felt as though walking on sand all the time.

A year ago last fall his eye trouble became worse—eyes saw double, and this double vision lasted for about two or three weeks, could hardly see across the house, could see double each way, to the right and left; would not see double when looking straight forward. After looking to the right or left it would take a little while to get the eyes pointed straight forward again.

March, 1896.—No heterophoria. V. D. = 20_{30} ; with +.50 C. axis 90° = 20_{20} . V. L. = 20_{10} ; with +.50 C. axis 90° = 20_{30} , to which was added +3.50 for near vision. A test with the perimeter shows a slight narrowing of the field for red and a central scotoma in field of left eye. Patient no longer gets dizzy, except in bed at night, when he is awakened by a great noise in the head, and will be dizzy until he can assume a new position. The glottis does not completely close in spasm, though he occasionally has a tickling spasmodic cough of short duration.

December, 1896.—Does not strangle, and the cough is slight and controllable. Vocal cords during phonation are parallel. When getting his breath after having spoken a few words his inhalations are audible. Mucous membrane of the throat is pale. Vocal cords during phonation are not steady. The left vocal cord is in the median line and remains there during the use and non-use of the voice. During phonation the right vocal cord will come up into position parallel with the left, and then by a series of unsteady movements will go away from its partner. During inhalation the left cord remains in the median line and is sucked downward like a valve, while the right vocal cord is curved outward, being somewhat sickle-shaped, and is valve-like but not depressed as much as the left.

May 11, 1897.—The patient has had but one attack of strangling in several months, no dizziness, no pains, no difficulty in micturition or defecation, no hemorrhoids. The field of vision remains about the same. The scotoma in the right eye is not now demonstrable, and that in the left eye is much smaller, being but a mere line extending from the point of fixation half way across the nasal portion of the field.

SALIVARY CALCULI.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY W. FREUDENTHAL, M.D.

PRESIDENT OF THE GERMAN MEDICAL SOCIETY OF THE CITY OF NEW YORK.
NEW YORK, N. Y.

Salivary calculi are, as a rule, easily recognized, although they are not of frequent occurrence. They are most frequently located near the buccal end of Wharton's or Steno's duct, and often have a definite outline and shape, rendering their detection by palpation usually easy. There are, however, a number of cases recorded in which their discovery was made by mere chance. Such an instance occurred in my practice. In two of my cases the diagnosis was easily made.

It appears that the growth and formation of salivary calculi begin years before their detection, and in this respect their character is quite in contrast to the stones found imbedded in the nasal cavities, which latter reach a large size after sometimes a growth of only a few months. The secretory function of Steno's or Wharton's duct and of the nasal cavity proper are not only different, but the foreign bodies found there are of different sizes. Sometimes these ducts contain large stones, without in any way producing symptoms, or in any sense annoying the patient. Such an instance is the following case:

Case 1.—Mr. A. F., 23 years of age, for the last six years a professional clarionetist, came to me last winter, in the height of his season, complaining of a cold, contracted two weeks before, and in consequence of this an abscess had formed, as he be-

lieved, under the tongue. On examination I found a swelling about the size of a hen's egg in the left sublingual region. No hard substance could be felt at all. Believing that I was dealing with a ranula, I made a long incision through the buccal mucosa. A mass of fetid pus escaped, and, to my surprise, the end of a stone, oblong in shape, appeared in the opening. It was readily extracted. It undoubtedly came from Wharton's duct, judging from its contour. There is nothing unusual in its size and weight.

After thoroughly cleansing the abscess cavity, I passed a probe, and was surprised to find evidence of another stone situated deeply within the tissues of the submaxillary gland. My first effort to extract it resulted in failure, as it slipped back further in the cavity. My second attempt, however, was successful. The stone was irregularly oval and about as large as a cherry. One would suppose that a person whose mouth is constantly in action by reason of his professional occupation, would be able to detect anything of an abnormal character in it. Yet in this instance the patient never suspected anything whatever, until two weeks ago, when as he states, he contracted the cold, which most likely caused the abscess about which he consulted me. He is positive that before contracting his cold he never felt anything unusual in his mouth.

As an illumination of the powers of endurance, it is interesting to state that my patient, a weak man at best, not only followed his usual vocation as a clarionet player up to the day on which the calculus was discovered and extracted, but also played his musical instrument on the evening after the operation despite the fact that there was a large iodoform tampon in the old site of the calculus. There are on record other instances where a supposed "cold" led to the detection of salivary calculi.

Mr. Carver¹ removed a stone from a man 70 years of age, who had noticed some tenderness in the sublingual region only for about five or six weeks.

Demons² found a stone the size of an olive in Wharton's duct, which produced no symptoms until three weeks before its removal.

There are, on the other hand, cases recorded in which the stone had made its presence felt for several years before its final extraction. Alfred Smith and Alex. T. Scott³ reported a case in which a tumor had been first noticed by the patient seven years before, at which time it was the size of a pea.

Jos. Dixon⁴ describes the sufferings of his wife, who had noticed a swelling under the tongue for fifteen years. Mr. Alexander Bruce⁵ removed a stone of "considerable dimensions," as he states it, although it weighed only $11\frac{1}{2}$ grains. In this instance the patient had felt it fourteen years previously. Dr. Webb's⁶ patient felt a small lump sixteen years before being operated upon. Dr. Padiou's⁷ patient felt it for twenty-five years, and Dr. Schuster's⁸ patient for forty-four years (!)

It is known that patients suffering from salivary calculi frequently obtain relief from their symptoms by squeezing out the pus and mucus which surround the stone and fill the cavity, into the mouth, from which they expectorate it or unconsciously swallow it. Thus, we can understand in Jos. Dixon's case the attacks of dyspepsia lasting for fifteen years, which were not amenable to treatment. The patient apparently swallowed the secretions which she pressed out from the glands.

Other symptoms caused by the stones are pain increased by movements of the jaw such as during mastication, and from retention of saliva shortly after mas-

tication. Still another symptom occasionally encountered is difficulty in breathing. That this last symptom is sometimes dangerous to life is proven by the case of J. W. Hulke, and my second case.

Hulke⁹ treated a young lady who had a tumor under the tongue which had been growing for the last six years. This tumor sometimes enlarged temporarily to such proportions as to threaten suffocation. At times there would be a discharge into the mouth, followed by the return of the swelling to its former size. The patient indicated by her statements that the stone had nearly suffocated her.

The following case which came under my observation, illustrates this last point:

Case 2.—Mr. N. S., aged 45 years, had been suffering two and a half years before he noticed a swelling under the tongue. This swelling grew steadily, and occasionally caused him great pain. For the last ten days the pain and swelling had grown worse. During the night he snored so loudly that he had to be wakened, and on these occasions his face would become markedly cyanotic. The patient was tall and very stout, and had the hoarse voice that characterizes the chronic alcoholic. On examination the tumor was found to project slightly from under the tongue and to extend along the right of the frenulum, reaching to the floor of the mouth, backward between the root of the tongue and the angle of the jaw, at which spot it appeared to be adherent to the buccal mucous membrane, simulating the case described by Hulke. By palpation fluctuation was elicited, and a hard mass could be plainly felt within it. I was quite sure that we had to deal here with a salivary calculus which had formed in the beginning of the main duct, and I advised its removal. For obvious reasons the patient refused and went home. His heart and lungs were normal.

Several weeks later I received a note from his physician, stating that the patient had died. The night preceding his death he had imbibed more freely than usual, and then retired. Having fallen asleep, he began to snore so loudly that his wife awoke. She found the patient breathing with great difficulty, while his face was black and blue. She tried to awaken him, but failed. She had a physician called; but the patient died of suffocation before medical aid reached him. An autopsy disclosed an almond-shaped salivary calculus, imbedded in a pus cavity. Death no doubt resulted indirectly from its presence; for on previous occasions he would invariably get rid of the pus that had accumulated in the cavity by coughing or hawking it out, and in this manner relieve himself of the cause of his dyspnea. But on the fatal night he was so fully under the influence of liquor that he could not arouse himself from the stupor caused by it, and thus succumbed.

I remarked in the beginning of this paper, that when I compared the sizes of salivary calculi and rhinoliths that I believed that the majority of these deposits owe their formation to the fact that a foreign body enters the duct or gland itself.

When Clinton Wagner¹⁰ says: "These concretions are formed by the deposit of earthy salts from the saliva in the excretory ducts leading from the gland or in the body of the gland itself, and that the cause of the deposit is an obstruction to the flow of saliva either to or through the excretory duct," he overlooks the primary cause of their formation, *i. e.*, a foreign body. Around this foreign body is deposited layer after layer of earthy salts. This obstruction causes a retention of the salivary secretion. I do not, however, claim that this process obtains in all instances of salivary calculi, but in the majority.

Professor Ribbert of Bern, found that a hair of a

toothbrush had forced itself into Wharton's duct, thus giving rise to the formation of a salivary calculus around it.

In several other instances the same causative element was found. Hulke removed a stone weighing 76 grains. Its broken surfaces exhibited concentric rings around a small, black, central speck. This speck was a fragment of wood.

It must be true that in certain calculi no central foreign body can be demonstrated, because it has undergone chemical changes. Galippe reported a case of spontaneous discharge of a stone from Wharton's duct. This calculus had concentric strata without a kernel being found. But he found microbes, already described by Malassez and Vignal, in these deposits.

One case is reported by Wertheimer¹¹ in which an abscess formed during eating. The patient while eating blueberries suddenly noticed a tumor in the right submaxillary region, and at the same time a burning sensation in the mouth. These symptoms always appeared during mastication. Finally, among greenish cheesy masses, the berries were found. Here stones had not yet formed, so, properly speaking this case does not belong here, but it shows how often foreign bodies enter Wharton's duct.

Case 3.—Mr. M. P., 57 years of age, merchant, of moderate habits and enjoying good health, had noticed for some time a small lump in the left submaxillary region. For the last three months it had grown steadily and had become painful during and after mastication. A simple incision was made, and a small oval-shaped stone removed. In cutting it open, concentric rings were seen and a very small piece of wood in the center. It was ascertained that the patient had been for years in the habit of chewing toothpicks, thus most likely forcing the foreign body into Wharton's duct.

These cases certainly prove that the formation of calculi around a foreign body does occur in these as well as in other parts of the human anatomy. That there are other causes for their formation there is no doubt, an increase or decrease in the quantity of saliva is an important factor.

A case of Thomas Ballard¹² is of interest: A young lady suffered from the effects of a buccal abscess which had opened spontaneously. Two small calculi were removed from the abscess cavity. It was learned that eleven years before she was salivated during an attack of jaundice. It is probable that this salivation caused a swelling of the excretory duct of the gland, then a retention of saliva and gradually the formation of a stone.

Just as increased flow of saliva may tend to produce a calculus, it may also tend to wash away a nucleus in the duct, around which salty deposits might form. This was the case with a patient of Kurz's, who had taken pilocarpin internally. The increased glandular excretion washed out a calculus from Wharton's duct.

In conclusion, I also believe that the submaxillary is more often the site and seat of calculi than the parotid gland, because the secretion of the former gland contains a comparatively larger proportion of mucin, a substance which seems to possess considerable adhesive properties, and seems to favor the deposit of inorganic salts. This belief is confirmed by the fact that the usual site of the calculus is just at the outlet of the salivary duct on the buccal mucosa, a point which furnishes a ready ingress for foreign matter.

DISCUSSION.

DR. SOLLY—I once found a calculus in the submaxillary gland. I have never seen a case reported where the calculus was imbedded in the body of the gland. An incision was made following up the duct and the stone was felt by the finger, imbedded in the gland, and was then forced into the mouth and removed. The stone was about the size of a chestnut and weighed twenty-five or thirty grains.

DR. FREUDENTHAL—I am sure that there are several cases on record where the stone was in the body of the gland. Dr. Bull of New York has one, and there is a case reported by another surgeon whose name I do not recall, in which the stone could not be reached from the inside of the mouth and he had to make an incision from the outside.

AN UNUSUAL CASE OF BLOOD CYST OF THE POSTERIOR NARES.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN N. MACKENZIE, M.D.

NEW YORK, N. Y.

The patient was a young lady of 23. As a result of the imperfect extraction of a tooth, there was necrosis of the jaw, with subsequent exfoliation of bone, leading to a more or less complete obliteration of the lower portion of the antrum. This had happened five years before consultation. For three years before consultation she had suffered with symptoms referable to the orbit and antrum. On examination a small glistening point was seen, resembling the appearance seen in fibroma of the nasal cavity. The right side of the nose was occluded. The mass looked very much like a child's toy balloon. The envelope of the cyst was extremely attenuated looking as if it was scarcely a line in depth. I made an appointment with her to return the same day, but in the meantime a spontaneous rupture occurred, and when I examined her the next day I was unable to find any trace of the growth. The inflammatory process which originated the trouble probably started in the antrum as a result of the necrosis of bone, and from this the edema and the subsequent formation of the cyst had resulted. I consider this a unique case. Some cases of large serous cysts have been reported.

AN ETIOLOGIC STUDY OF ATROPHIC DISEASE OF THE UPPER AIR PASSAGES BASED UPON AN EXAMINATION OF TWO HUNDRED CASES.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY J. L. GOODALE, M.D.

BOSTON, MASS.

In the following paper I desire to invite your attention rather to the predisposing than to the immediate causes of atrophic states of the nose, pharynx and larynx. The statements current in our recent textbooks that certain classes of persons under certain conditions are particularly liable to these conditions appear to be derived from general impressions. Since under such circumstances, a few positive examples are apt to outweigh unduly a large number of negative and therefore easily forgotten ones, I undertook recently to submit the current statements to the test of a systematic examination. For this purpose 200 cases of atrophic disease of the nose, pharynx or lar-

ynx were investigated carefully with reference to the following points.

1. The relation of these states to age, sex, sexual functions in the female, and general nutrition.
2. The influence of a normal patency of the anterior nares.
3. The influence of the inhalation of an insanitary atmosphere.
4. The influence of pre-existing local or general disease.
5. The relation to associated hypertrophic states of the neighboring mucous membrane or lymphoid structures.

In the consideration of atrophic disease, I have at the outset excluded the following conditions:

1. An imperfect development of the intra-nasal structures, especially of the turbinates, occurring in chlorotic young women, and not associated with nasal obstruction or chronic inflammation of the nasal mucous membrane. For purposes of convenience, I have called this condition congenital hypoplasia of the nasal turbinate, since, although histologic examinations are wanting, an analogy is very directly suggested to Virchow's congenital hypoplasia of the female sexual and vascular systems associated with chlorosis.
2. I also exclude an imperfect development of the intra-nasal structures occurring in post-nasal obstruction, probably due as I have previously suggested¹ to the absence of normal respiratory alterations in intra-nasal air pressure requisite for proper nutrition.
3. There are to be excluded the anemic conditions of the nasal mucous membrane, secondary to general malnutrition, particularly seen in phthisis; also
4. The pressure atrophies from septal deviations and new growths.
5. Finally, atrophic states associated with syphilitic lesions in the vicinity.

With the exception perhaps of the last, such states are the result of altered nutrition and non-inflammatory in nature. They are therefore sharply to be distinguished from the genuine atrophy at present under consideration. The five conditions just referred to although recognizable when occurring typically may, if inflammation supervenes, closely resemble clinically mild forms of genuine atrophy. This possible source of error is to be borne in mind in the examination of cases.

For purposes of classification it appeared most natural to divide the cases of true atrophy into the following groups:

1. Atrophic states of the nasal structures, not accompanied by decomposition, whether or not associated with atrophy of the pharynx or larynx.
2. Atrophic states of the nasal structures with characteristic fetor, whether or not accompanied by atrophy of the pharynx or larynx.
3. Atrophic or dry conditions of the pharyngeal mucous membrane unaccompanied by atrophy within the nose.

For convenient designation these conditions will be called respectively, non-fetid atrophy, fetid atrophy and pharyngeal atrophy.

The relations of these atrophic states to sex are *non-fetid atrophy*, males 20, females 54; *fetid atrophy*, males 28, females 71; *pharyngeal atrophy*, males 12, females 15.

¹ An Experimental Study of the Respiratory Functions of the Nares; Boston Medical and Surgical Journal of November 5 and 12, 1896.

Age.—Since the age at which characteristic symptoms first developed is of more value than the age at the time of examination, a table of this is given.

AGE OF DEVELOPMENT.						
AGE.		MALES.			FEMALES.	
Between		Non-fetid.	Fetid.	Phar.	Non-fetid.	Fetid. Phar.
1 and 4	(3) 1	(2) 1	...	(6) 3	(5) 1	...
5 and 9	(4) 3	(9) 1	...	(8) 3	(28) 1	...
10 and 14	(4) 3	(8) 7	...	(2) 7	(22) 8	...
15 and 19	6	(2) 8	(4) 2	(2) 11	(5) 17	(2) 1
20 and 24	3	(3) 1	(2) 5	9	(1) 19	(1) 2
25 and 29	3	5	1	10	(3) 10	(3) 2
30 and 34	1	3	1	7	4	3
35 and 40	3	3	...	3	7	5
Above 40	3	3	4	5	(5) 5
Doubtful Duration	(6)	(4)	(6)	(36)	(7)	...

(Figures in brackets indicate age when characteristic symptoms appeared; unbracketed figures indicate age at time of examination.)

Sexual functions in the female—*Character of menstruation.* Non-fetid atrophy (54 cases): Menstruation regular and normal, 27 cases; menstruation irregular or scanty, 11 cases; menstruation not appeared, 6 cases; answers doubtful 10 cases.

Of the fifteen pharyngeal cases only one had noticed increased dryness of the throat during menstruation. A single case only, one of fetid atrophy, had noticed improvement after establishment of menstruation.

No case had noticed any change following marriage. In one case of non-fetid and one of fetid atrophy the symptoms greatly diminished after childbirth.

General health and nutrition.—In the seventy-four non-fetid cases it was noted that six males and thirteen females exhibited distinctly poor health and nutrition, the remainder being well up to or above the average.

In the eighty-seven fetid cases, twenty-four showed poor health and nutrition.

In the cases of pure pharyngeal atrophy, three cases, all females, showed poor health and nutrition.

The inhalation of an insanitary atmosphere and the previous existence of local or general disease were inquired into in all cases, but owing to the low degree of intelligence possessed by many of the patients, as well as for other reasons, the answers afford infor-

Chart showing absolute frequency of atrophic states of upper air passages in 200 cases at different ages.

Age of favorable commencement of affection, male ———. Age of favorable commencement of affection, female — — — —. Age at time of examination of male Age at time of examination of female — — — —.

Fetid atrophy (71 cases): Menstruation normal, 36 cases; menstruation irregular or scanty, 18 cases; menstruation not yet appeared, 8 cases; answers doubtful, 19 cases.

Pharyngeal atrophy (15 cases): Menstruation normal, 7 cases; menstruation scanty, 2 cases; answers unsatisfactory, 6 cases.

The patients were questioned with regard to the existence of any connection between the intensity of the atrophic symptoms and the period of menstruation.

In the fifty-four non-fetid cases, two only had noticed any increased dryness or discharge during menstruation, seventeen intelligent patients were sure that no such connection existed, and the remainder had never given the matter attention.

In the seventy-one fetid atrophies, nineteen had observed increase of crust formation during menstruation, nineteen were positive that no change occurred, three were sure that the nasal discharge diminished and was less fetid, the remainder being doubtful.

mation of doubtful statistical value, and have therefore been omitted.

Abnormal patency of the anterior nares.—The presence of a configuration of the anterior nares permitting abnormally free inspiration was noted with reference to the following points:

1. An upturned or tip-tilted condition of the anterior nares.
2. Abnormal wideness of the vestibule.
3. Development of the vibrissae.
4. Degree of laxity of the constricting band.

Of the twenty male non-fetid cases, one showed a moderate and five a considerable tilting up of the anterior nares.

Of the fifty-four female non-fetid cases, twenty showed this condition moderately, and two markedly.

In the fetid cases, out of twenty-eight males there was moderate tip-tilting in seven and marked in seven

cases, while among seventy-one females this condition was moderate in sixteen and marked in twenty-three.

A widening of the vestibule appeared abnormally marked in the non-fetid cases among eight males and twenty-one females, in the fetid cases among eighteen males and forty-two females.

The vibrissæ appeared less abundant and smaller than normal in the non-fetid cases among nine males and fifteen females; in the fetid cases among sixteen males and thirty-six females.

Of the pharyngeal cases two females and one male showed abnormal patency of the anterior nares in these particulars.

The constricting band of the vestibule appeared unusually lax or deficient in the non-fetid cases among eight males and twenty-one females; in the fetid cases, among seventeen males and forty-three females.

The relation to hypertrophic states of the neighboring mucous membranes and of the lymphoid structures.—Of the non-fetid cases, one showed distinct hypertrophy of the nasal mucous membrane directly contiguous to the atrophy, while three cases showed a polypoid condition of the middle turbinate in association with atrophy of the lower turbinates.

Of the fetid cases, only one showed a hypertrophic condition in association, this being an enlargement of the lower turbinates posteriorly.

On the other hand, the cases of pharyngeal atrophy showed a very different condition of affairs, for seven females and five males, ranging in age from 23 to 72, presented a distinct hypertrophy of the nasal mucous membrane.

With reference to enlargements of the adjacent lymphoid structures, adenoid hypertrophies or remains were present in nineteen non-fetid, in seven fetid and in three pharyngeal cases.

Hypertrophy of the faucial tonsils was present in nineteen non-fetid, in twenty-two fetid and in six pharyngeal cases.

Enlargement of the lingual tonsils was present in eleven non-fetid, in fourteen fetid and in three pharyngeal cases.

Time does not permit an enumeration of some other results of this work, such as the relation to the preceding points of unilateral forms of atrophic rhinitis, or the relation sustained to them by different localizations of the atrophic process in the nose, pharynx and larynx.

Conclusions.—In recapitulation, the following facts are evident.

Both fetid and non-fetid atrophies are more than twice as common in females as in males, while pure pharyngeal atrophy occurs with nearly equal frequency in both sexes.

Both fetid and non-fetid atrophy begin with greatest frequency between the ages of 5 and 15, while the pure pharyngeal form was not found before 20, and occurred irregularly from that age up to 72.

A distinct relation is sustained to the sexual functions in certain females. While menstrual anomalies are uncommon, perhaps not more frequent than in an equal number of females with healthy air passages, yet in 4 per cent. non-fetid and in 26 per cent. fetid cases the atrophic symptoms were increased during the catamenia, while in 4 per cent. of the fetid cases the symptoms were diminished.

The establishment of the menses and the occurrence of pregnancy improved the symptoms in isolated instances.

In all forms, three-fourths of the cases showed good health and nutrition.

Unusual patency of the anterior nares was found in 40 per cent. non-fetid, in 60 per cent. fetid, and in 10 per cent. cases of pharyngeal atrophy.

Distinct hypertrophy of neighboring portions of the nasal mucous membrane occurred only in isolated instances among the fetid and non-fetid cases, while among the pharyngeal cases it was found in about half the total number.

Hypertrophy of the pharyngeal tonsil occurred in 20 per cent. of the non-fetid cases, in 7 per cent. fetid, and in 10 per cent. pharyngeal.

Hypertrophy of the faucial tonsils occurred with equal frequency among the three forms, namely in about 20 per cent.

A review of the preceding results indicates that the weight of their testimony is distinctly against the theory that non-fetid and fetid atrophy is the sequel to a pre-existing hypertrophy, at least to a hypertrophy as we ordinarily understand the term. On the other hand, the facts are in direct corroboration of the supposition that the process is primarily an atrophic one, whether we consider it to originate in the action of a specific micro-organism or not.

In pure pharyngeal atrophy it is more difficult to draw conclusions, owing to the greater complexity of the conditions. Without discussing its etiology, we have reason, from these investigations, to suppose that a form of atrophic pharyngitis exists which differs in nature and origin from the conditions called fetid and non-fetid atrophic disease of the upper air passages.

3 Fairfield St.

DISCUSSION.

Dr. FREUDENTHAL—I think Dr. Goodale did not lay enough stress on the question of the sanitary condition of the atmosphere. It is remarkable what an amount of bad air otherwise well educated people will stand. The air that we inhale is moistened in the nose. In order to fulfil its work, the air must have 50 or 60 per cent. of relative humidity. In summer the air is filled with moisture, but in winter it is not. In New York the atmosphere in winter contains not more than 10 per cent. of moisture. It is very probable that such an atmosphere will dry the nasal mucosa. The lack of moisture in the air can be made up by the nose for a time, but if the condition goes on too long the parts dry out. I am positive that the dry atmosphere that we breathe in our houses for six months of the year is one of the principal factors in atrophic nasal disease.

Dr. SCHEPPEGRELL—In New Orleans we have a very humid atmosphere, but I have no reason to believe that atrophic nasal disease is more rare than elsewhere. Dr. Goodale has no faith in the fetid atrophic rhinitis being a consequence of hypertrophic rhinitis. In ozena I have never been able to see any relation between them.

Dr. RICHARDS—In the mills in Fall River a moist atmosphere is necessary in handling the yarn, and yet I have a great many cases of atrophic rhinitis in my practice. Among the children who work in the mills it is common.

Dr. SOLLY—In Colorado, where the air is very dry, atrophic rhinitis is common, but hypertrophic rhinitis is not.

Dr. FREUDENTHAL—There is often a large percentage of humidity in the outside air in New York. I spoke particularly of the air in the houses, which we breathe in winter.

Dr. WOOLEN—At the first meeting of this Section that I attended, I stated that I did not believe there was any such thing as a tonsil in a healthy throat. I have also for a long time doubted whether there is any such thing as atrophic or hypertrophic rhinitis. The pathology of these cases is to be found in a disturbance of nutrition of the parts. There is a pathologic process going on in the fibrous structures underneath the membranes not essentially inflammatory. If we study these cases we will find that a process of hypertrophy is started which does not need to go far before it frequently turns in the other direction and becomes atrophy by contraction of these fibrous elements. I have long ceased to regard these

cases as atrophic and hypertrophic rhinitis, but intra-nasal atrophy and intra-nasal hypertrophy.

Dr. HOFFMANN—If young children are closely observed it will be found that hypertrophic conditions of the nose and throat commonly exist.

Dr. GOODALE—It seems to me that the views of the different speakers may be brought into harmony when we consider the fact that under different conditions of the atmosphere the disease occurs with equal frequency. This may be explained by the great adaptability of the mucous membrane of the nose. This membrane has great powers of moistening the air. I have known individuals who were reared in a dry climate and those who were reared in a moist climate to have, normally, the same conditions in the mucous membrane. The predisposing causes of the disease are to be found primarily in the lack of resistance of the structures of the nose. This fact is corroborated by the greater frequency of these conditions among females, as a consequence of the greater delicacy of the mucous structures. My own view is that the cause may eventually be found in some bacterium.

MODERN PATHOLOGY AND THERAPY OF ACUTE RHINITIS.

Presented to the Section on Laryngology and Otolaryngology, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY A. R. SOLENBERGER, M.D.

CHICAGO, ILL.

In creating a rational and scientific basis for the treatment of acute rhinitis, we may assert the same general principles, which are fundamental to all other diseases, viz., that if the constitutional condition of the individual is such as to render him free from the predisposition, there is no such thing as an exciting cause for that individual. This is almost self evident in the case under consideration; for there are those in every climate, exposed to all the exciting causes, who never suffer from colds. The physiologic balance between the digestive, nervous and circulatory systems is perfect; they are immune to all external influences; to heat or cold, to atmospheric perturbations and micro-organisms. This immunity means perfect adaptation of the systems of the individual to his artificial environments; it means perfect tissue resistance to all disease producing causes. Here, then, we have a condition which is incompatible even with a predisposition to nasal inflammations.

It would be rational, then, to direct our treatment to the removal of the predisposition by restoring the normal physiologic balance between the systems and that of the integrity of the tissues. Our therapeutic measures should be directed toward any cause that is found disturbing this physiologic equilibrium, or disintegrating the tissues.

To locate and give value to these disturbing elements is to bring to light the true causal conditions of acute rhinitis. By utilizing modern scientific methods of diagnosis, we have come to see these causes in embryo behind and eventually within the digestive, the nervous and the circulatory systems. They constitute those fundamental conditions which have long been known as pathologic entities, but they have not usually been recognized as being responsible for nasal inflammations. These basal conditions are the temperaments and diatheses; we know them as the nervous, the bilious and phlegmatic; the rheumatic, strumous and tubercular.

Scientific methods of diagnosis show us conditions within conditions—conditions within the temperaments and diatheses, which manifest themselves, first in the state of the nerves and ultimately in the blood. Broadly speaking, the first link in the pathologic

chain of acute rhinitis will be found primarily in any influence whatsoever that will unduly dissipate the nerve force. This may be a pathogenic germ—any poison in the blood—any dietetic regime that, from indigestion and mal-assimilation results in mal-nutrition and retention in the blood of half assimilated and, therefore, toxic products; or a diet that reduces the alkalinity of the blood; or it may be midnight dissipation, mental or physical overwork—any influence that constitutes a nerve irritant becomes a nerve exhaustor, a peripheral and finally a central paraly-sant.

To trace one of these causal influences arising from the transgression of a physiologic law, let the transgression be that of mental overwork or a restricted nitrogenous diet. In the one case you have a direct central nerve exhaustor, in the other an indirect nerve exhaustor from the presence in the blood of a peripheral irritant, perhaps the uric acid crystal or superfluous peptones. In either case, there is first nerve irritation, the nerve grip upon the blood vessels is tightened, the vascular membrane of the respiratory tract offers the least resistance, and that of the nasal cavities the least of all; engorgement in the nasal cavities thus obeys a natural law; for, if now the irritating action continues in force, nerve exhaustion ensues, the nerves then loose their grip upon the blood vessels, there is vasomotor paralysis, the vessels have collapsed, filled with thickened and perhaps acid blood.

Here we have one pathologic pyramid of a well developed cold in the head, in which the inflammation of the Schneiderian membrane constitutes simply the apex, and the abnormal condition behind or within the digestive, circulatory and nervous systems forms the constitutional base.

There are, then, two primary conditions that come before the eye of the rhinologist in the treatment of acute rhinitis; 1, nerve irritants or exhaustors; 2, tissue integrity. Nerve exhaustors are as various as they are numerous, but the labor of detecting them is greatly simplified by the fact that they nearly all act through and culminate in the temperaments and diatheses. A vicious circle can always be seen in operation: nerve exhaustion, from causes outside the blood, produces an abnormal tissue chemistry; this results in waste and obnoxious products being thrown into the blood, which by their irritant action still further lower the nerve force and weaken the remote organs; these latter become reservoirs for accumulated by-products which are returned to the blood with increased irritative qualities.

If these organs happen to be the liver or kidney there will be retention of urea and uric acid, resulting in reduced alkalinity of the blood—a condition most favorable for mucous membrane inflammation of the respiratory tract. Thus the center of the vicious circle acts upon the periphery and the periphery upon the center.

If, in the past, failure has been the rule in the treatment of acute rhinitis and the disease has gone on and become the base of many serious chronic conditions, it is due to the fact that the deep causal elements have not been sought; the causal links in the pathologic circular chain have not been found; the pernicious circle had not been broken.

These considerations, however, do not in the least displace local treatment; but they do speak for rational and conservative local measures. If the pathologic strata in the Schneiderian membrane has become many

times superimposed, or if there exists nasal stenosis from whatever local cause, or if there is disease of the accessory sinuses, local operative treatment is rationally demanded; but even in these cases unless constitutional treatment goes *pari passu* with local measures, the apex is removed while the base of the pyramidal structure remains unshaken.

This one law, this fundamental law, controlling vital tissue, we must constantly remember; that tissue integrity, tissue resistance always determines, not only whether there shall be any inflammation at all, but whether that inflammation shall terminate as simple catarrhal, or go on to polypoid, suppurative or malignant degeneration. In the presence of this law the only treatment that will permanently avail is that which is aimed at the base of the diseased structure, —to the restoration and maintenance of the soundness of the tissues. The history of a nasal polypus or of a deviated septum runs a long way down the pathologic chain, and will frequently be seen to have had its beginning in some constitutional taint in which the soft tissues and bones went wrong. It is not claimed that this law of tissue resistance of the organism is a new one; it is as old as modern pathology, but the plea is that it be made the basis both of preventive and active treatment of acute rhinitis. These considerations, which in the minds of some are still theoretical, have to me become substantiated facts, from the rather large opportunity I have had in the past few years for the study of typical cases, and applying constitutional treatment.

During a period covering the six winter months of 1895 and 1896, when the atmosphere of Berlin was unusually damp and cold, and still mildly charged with the influenza bacillus, the clinics of Fraenkel and Krause were constantly crowded with patients suffering from acute colds. In the numerous cases, which then came under my observation, I sought to secure an etiologic classification, based on answers to questions put to the patients, and by other usual tests to prove the presence, or absence, of the temperaments and diatheses. In the notes taken the disease was thus classified as subjective, when the cause or causes were purely internal; or as objective when they were external, and mixed, when the cause or causes were both internal and external. In referring to the cases which were regarded as typical, and which were thus carefully classified, an approximate résumé would be as follows:

Seventy per cent. clearly pointed to one or more constitutional conditions as the cause, while 15 per cent. appeared to be due to one of the many external irritants, through the medium of the atmosphere or contagion; 90 per cent. of these cases were acute exacerbations engrafted upon chronic conditions in the nose and throat, and always gave the familiar history of repeated attacks. Those which appeared to be due to pure and simple external exciting causes gave the history of the inhalation of fumes of irritating drugs or other atmospheric irritants, or extension of inflammation from bronchitis or laryngitis; of measles, scarlatina, whooping cough, or of the inhalation of hot, dry air or exposure to cold and to the influenza bacillus. In the laboratories of Dr. Alexander repeated microscopic examinations of the secretions were made to discover the bacillus, which Hajeck believes to be responsible for acute rhinitis, but even in initial cases many other bacilli were seen, among them, the pneumococcus of Freidlaender. A few trials to produce the dis-

ease in animals by Hajeck's diplococcus completely failed. In about 25 per cent. of the cases, classified as constitutional, one or more of the exciting causes were found to be present, but in much the larger part no such history could be elicited; there was always the familiar answer "I don't know how I caught cold;" but there was always the significant fact that the constitutional cases gave the history of repeated attacks, while those cases which were put down as local had seldom suffered from colds. We have spoken of scientific methods of diagnosis—that they enable us to ascertain the true causes of acute rhinitis, and that they confirmed the above principle of treatment. It must be acknowledged, however, that all modern scientific methods, advanced as they are, can only give us an approximate etiology, but the claim is that treatment based upon this has been eminently successful in effecting a permanent cure of acute rhinitis and its multitudinous concomitants.

NON-SPECIFIC PERFORATION OF THE NASAL SEPTUM.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY J. R. STRAW, M.D.
ASHLAND, WIS.

Perforation of the septum, either specific or non-specific, seems to have been considered of so little importance that few if any of our authors have given it more than a passing notice, in fact, all that I have consulted have dismissed it with only a paragraph or two at most.

Before I located on the south shore of Lake Superior, nearly four years ago, I had been taught to believe that practically all perforations of the septum were of specific origin, and up to that time was satisfied with that theory, and for several months after locating in Ashland, Wis., I continued to treat my cases accordingly. While I was soon impressed by the large number of perforations I found, I also discovered a supposed satisfactory explanation for them. Several Indian reservations surrounding our city, the inhabitants of which I had no doubt from another and correct ancient teaching, were thoroughly infected with syphilis, and that it would be somewhat disseminated among the superior race; however, after having lived there long enough to become acquainted with the people I found that the average white man in that section was about as moral and virtuous as elsewhere, and has little or no occasion and no disposition for social or other connection with this race.

After I had become well acquainted with the descendants and antecedents of some of the people who bore this "suspicious mark," I was forced to abandon the theory of syphilis in a number of them, and look for some other cause.

Very few of my patients were aware of the perforation, but came to consult me about their "catarrh in the nose," or some throat or ear trouble.

A large number of these perforations were in the anterior and cartilaginous portion of the septum, and a great many of them had cicatrized and showed no disposition whatever either to break down or advance, and even if there were unhealthy granulations, specific treatment did little or no good, so I began to resort to the galvano-cautery, and a protective dressing, such as unguentum. In a short time, without the

specific treatment, the season being propitious, the borders of the perforations became smooth.

In regard to the etiology of these cases, I believe it is primarily due to our climate, which during three or four months of the year is extremely cold, the thermometer ranging during this time, from 0 to 30 and sometimes even 40 degrees below, and one who is out any length of time is liable to have the tip of the nose frozen; this is usually considered a very trivial matter. I think this freezing and thawing process has a tendency to produce erosions of the mucous membrane and breaking down of the cartilaginous portion of the septum, or the inspissated mucous adhering to the anterior portion of the septum and the patient's continued picking at it abrades the surface and leaves the sensitive papillæ exposed to a temperature 15 or 20 degrees below zero, which, I have no doubt, freezes them every time the patient exposes himself to this extreme cold.

I have treated a number of cases during my three winters in this section, that were going through the disintegrating process. I at first thought that to destroy or burn over this denuded surface would cause it to heal, but after repeated trials discovered that this mode of treatment was only adding fuel to the flames, and that it was useless to do anything with the view of effecting a cure during the winter months, and I now do nothing more than protect the parts with some simple ointment and have the patient plug the affected side with cotton whenever he goes out of the house if the weather is cold. When the winter is over, which is usually about May 1, I then apply the galvanocautery followed by an antiseptic dressing, which usually effects a cure.

PRACTICAL VS. THEORETICAL TONSILLOTOMY.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. HOMER COULTER, A.M., M.D., Ph.D.

PROFESSOR OF RHINOLOGY AND LARYNGOLOGY, CHICAGO CLINICAL SCHOOL, CHICAGO, ILL.

I doubt if there is any one subject in medicine and surgery more prolific in the way of literature than that of the tonsil. Hence to claim the addition of anything new to the subject would either savor of presumption or a limited acquaintance with current medical literature. In the past ten years there have been published over six hundred papers on various points relative to the tonsil. When we consider the volumes such an amount of literature means we are driven to the conclusion that either the tonsil is a most important organ, or it is an unusually frequent victim of pathologic conditions. The generally accepted reason is the latter; especially, since if we claimed the former we must of necessity be able to thoroughly establish its functional character and capacity.

A very brief, and necessarily somewhat incoherent, reference to the etiology of enlarged tonsil seems necessary. At the same time we must recognize the fact that any pathology we may seek to establish must be subject to criticism, since an uncertain physiology precludes the possibility of a reliable pathology.

Before inquiring as to what is, or what the cause of, an enlarged tonsil, let us fix in mind an ideal of normality. Opinions on this point are varied as is the

number of observers. Bosworth, Woolen and others claim there is normally no tonsil present on inspection. The greater number of writers, however, admit the existence of a protruding glandular or follicular collection of lymphoid tissue between the pillars of the fauces. Wagner has discussed at considerable length atrophy of the tonsils, but it is difficult to imagine how there can be a question of atrophy unless there was some considerable tissue previously present. In many cases there is not a real hypertrophy, but only an enlargement in the tissues already there; again, there will be a distinct hypertrophy, or actual formation of new tissue elements. It is not the purpose of this paper to discuss the cause of or differentiation of this condition. They do exist, and even hypertrophy and hyperplasia may frequently be seen in the same tonsil. Nor is it always an easy matter to distinguish between the two. Certain it is, however, both are pathologic and both demand and are amenable to surgical interference. A consensus of opinion would seem to indicate that the normal tonsil is a collection of racemose glands or follicles occupying and filling the space between the faucial pillars. Hence, when the tonsil protrudes beyond the pillar it is abnormal and pathologic. Remembering, however, that in very many instances the pillar is firmly adherent to the tonsil, we may then have a decided increase in the volume and yet no protrusion beyond the pillar.

I wish to particularly emphasize a point in the anatomy of the tonsil, the importance of such distinction will appear later. It has usually been referred to as an olive-shaped body. As a matter of fact, which dissection either on the patient or cadaver will demonstrate, it is more nearly almond-shaped, *i. e.*, somewhat flattened and larger at one end. This heavy end is uppermost, frequently buried well up under the pharyngeal aponeurosis.

Many excellent authorities have inclined to the opinion that a constitutional dyscrasia, usually the uric acid, is by far the most frequent and potent etiologic factor. The etiology, even though hypothetic, may be summed up in these two propositions: 1, an underlying constitutional dyscrasia; 2, a micro-organism in the follicles, producing in either case either an hyperplasia or an hypertrophy.

Dr. Stucky has claimed that, "of all diseases of the upper air passages none is more conducive to serious after-effects than pathologic tonsils." In health there is doubtless a certain amount of lubricant furnished by this collection of racemose follicles. But if it be diseased what good can come from its forcing upon the bolus of food or into the stomach an excretion of pus cells, cholesterin, epithelium and the various other products of waste and disease? Dr. Turck, demonstrated that, "the diseases of the mouth, nose and throat do often play a most important part in the etiology of chronic glandular gastritis." He further called attention to the fact that "the oral cavity, especially when infected, is a perfect incubator of disease germs." If such facts are demonstrable concerning the pharyngeal mucous membrane, how much more serious must be the secretions and excretions of the tonsillar follicles and crypts when diseased?

The symptoms and appearance of a tonsil demanding extirpation are matters of such universal knowledge that any further reference to them at this time seems superfluous. Admitting that its true etiology is the uric acid diathesis, the entire lymphatic system

in which we find the tonsils, joints, serous cavities and ileocecal glands is likely to be involved, and hence such admission only emphasizes the necessity for surgical interference. At the same time it should also warn us that pathologic tonsils compel us invariably to look for pathologic complications elsewhere in the system.

This leads us to the further fact, that in case a constitutional dyscrasia does exist it must be treated as such independently of any presumable tonsillar complication. A tonsillotomy, no matter what the method employed, will not complete the cure of such dyscrasia. Nor is there any doubt of the bad effect such dyscrasia or diathesis has upon the tonsil as well as upon the general health of the patient.

The neuroses due to enlarged tonsils are so varied, frequent and positive that it is no longer questioned that such do exist. Respiration is often affected. Phonation is most important, perhaps. I have never seen a case in which phonation was impaired that there did not occur a marked improvement in the voice, by thorough operation, both in its production and quality. Some laryngologists think the pitch of the voice is lowered by ablation of the tonsil. My experience, especially in professional singers, does not corroborate such a statement. I believe the added ease and increased clearness with which the voice is afterward formed will in reality raise the voice register by the same expenditure of effort, but only so in those cases in which the gland has been thoroughly eradicated. I can easily conceive why and how the register might be lowered in case the pillars were not freed from their adhesions, and a stump of hard unyielding, cicatricial tissue is left between the pillars. The ocular and aural disturbances attributable to this cause are frequently met with, and often yield most satisfactory results to the surgeon. Cough, I believe to be one of the most frequent and persistent of all the complications. It is, though not so frequently as formerly, urged by some presumably intelligent physicians, that the tonsil, if left alone, will atrophy later and thus cease to be a source of annoyance. But I scarcely think such advice is general, and could not be when once is seen the almost universal improvement in general health which their complete, and often even partial, removal produces.

A partial destruction of the gland, by whatever method is used, will oftentimes do more harm than good, and can not in any case accomplish all the possible good.

Whether the tonsil be a blood-elaborating organ, as some presume, or an assistant to digestion, or a lubricating fountain, or a leucocyte guard to the system, the presence of a pathologic condition precludes the possibility of its functional activity and demands removal, since no known medicinal remedy can restore that organic or functional capacity as it has become a veritable microbe trap. Though such a statement may seem to be rather sweeping and comprehensive in its compass, it admits of but few exceptions. As such, however, may be mentioned a tendency to or presence of malignancy, and even in the cases where surgical interference is deemed advisable, no other method affords nearly the hope of success of that suggested by this paper. Unusual vascularity or pulsation in the tonsil should be looked upon with suspicion in every instance. An acute inflammatory condition is always an indication for temporary postponement and at the same time is as positive an indication for sub-

sequent operation. A prevalent epidemic would also suggest temporary delay.

I will call your attention to the various methods which have received popular recognition at the hands of surgeons. Celsus was wont to gouge out the gland with his finger, evidently considering it a nucleated structure. This is, however, too barbarous to receive notice further than for its historic interest.

Doubtless the most popular method is by means of the guillotine, in one or another of its many forms. The objections to this instrument are that one can not remove all the gland, except in rare instances; it often leaves a bruised edge, sometimes ending in a slough; again, you are never quite certain of the amount of tissue you are going to remove; the pillars are very apt to be injured by it; the danger of hemorrhage is not insignificant, though not as great as when the bistoury is employed; if the tonsil be of that soft, flabby character often seen, or if it be small and adherent to one or both pillars the tonsillotomy becomes *perforce* practically useless. However, notwithstanding these real or apparent objections, I am convinced there is no method better adapted in case of young children under 8 or 10 years of age. Ignipuncture has attained more or less popularity, but it is an endless process at best, as one is never certain that all of the diseased follicles have been destroyed; it leaves a rough, ragged surface and the capacity for the absorption of toxins practically undiminished; it also leaves a portion of the tonsil to be absorbed, or to act as a focus for future inflammations. The cold wire snare has no advantages that are not possessed by other methods, and is in addition an extremely painful procedure; the danger of secondary hemorrhage is doubtless as great as by any other method. The cautery loop has been highly praised by Knight, Wright and others. It is certainly in many cases an excellent method, though some of the objections urged against the tonsillotomy are equally applicable to the cautery snare. The knife as a means possesses such patent and potent objections that more need not be said. In the same category may be placed the use of destructive caustics and strong astringents or interstitial injections of various medicaments, no one of which will more than partially remove or counteract the pathologic condition, and to the extent they fail in this particular, they, as well as any and all other methods, fall short in accomplishing the greatest possible good and are to just that extent impracticable. Every operator sooner or later, plainly or by inference, admits the necessity of removal of the entire gland if possible.

I am convinced that it is possible, for the very forcible reason that experience has demonstrated it most conclusively. Several years ago Dr. Pyncheon of Chicago suggested a method which was original, and which an experience of over two hundred and fifty tonsils in the past two years convinces me, possesses some advantages over all other methods yet suggested. Dr. Pyncheon gave a detailed account of the technique of his operation in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* for Nov. 22, 1890. Improvements in some minor points have in that time been suggested by the experience of both Dr. Pyncheon and myself, and I will briefly describe the operation as it is now performed.

The tonsils as well as the pillars have been thoroughly anesthetized by the external application of a 30 per cent. solution of eucaïn well rubbed in and

the submucous injection of a few drops of a 10 per cent. solution into the upper portion of both pillars and tonsil; the tonsil is drawn well out into the throat and the pillars are both carefully dissected away from the tonsillar body to about one-half its extent. The electrode point being entered cold and burning out, as a usual thing. The upper point of the tonsil is then grasped with an appropriate forceps and employing the same traction as above referred to, the distance from the carotids is not only increased but a much better view of the field of operation is then obtained, then by a slow dissection enucleate the part, much as an ophthalmologist would enucleate an eye. Remembering always that the large end of the tonsil is uppermost and well imbedded high up under the pharyngeal aponeurosis; and further, that any of its tissue left will not only detract from the cosmetic as well as practical results of the operation, but will as well probably be a source of future trouble. After thus completely separating the upper portion to the extent of one-third or one-half of the gland, cut off the loosened part and apply to the surface a solution of silver nitrate, 6 grams to 30 c.c. water, after applying a coating of campho-phenique. The amount to be removed depends on the size and condition of the tonsil as well as upon the temperament of the patient. I have found that there was but little complaint of soreness if not more than one-third or at most one-half of the tonsil was removed at one séance. The remainder is treated in a like manner at a subsequent sitting. The length of time between the steps of the operation differs, but in ordinary cases a week is quite sufficient for the healing process, especially if the patient comes to the office for treatment meanwhile. This inter-operative treatment is not so necessary as it is desirable, as I find a thorough cleansing and dressing of the wound assists materially in its healing, as well as reduces the soreness to a minimum. At these treatments the application of massage with a cotton-wrapped probe will help in giving a smooth surface to the parts after they have healed.

This method seems to be adapted to a larger percentage of cases for removal than any other now in common use. For the reasons already given it is the most practical in securing all of the pathologic tissue. The principal objections to its employment have been that it is not adapted to young children; this I consider the most valid objection that has come to my notice. The youngest patients I have known in which it was used were 10 and 12 years of age. The soreness and pain following the operation are not as severe as one might expect from treatment apparently so heroic. If the daily treatments are given, oftentimes there is no complaint whatever.

Very often the removal of one tonsil will effect a very considerable decrease in the size of the other. It will also have, at times, an almost miraculous effect upon a pharyngitis or other inflammatory action in the contiguous structures. Middle-ear difficulties seem especially amenable to its beneficent influence.

In closing allow me to call attention to several points which experience has taught me, will assist in giving the most desirable results.

1. Do only a small amount at each heating of the electrode—work five seconds and allow the patient to rest fifteen seconds.

2. Burn only where you can see just what you are doing.

3. Use an electrode bent at right angles and having

a fine point. (At least three electrodes are desirable for the operation.)

4. Do not attempt too much at one sitting.

5. A strong solution of silver nitrate is an excellent hemostatic in case there is slight hemorrhage.

6. Be sure the electrode is thoroughly heated when you attempt to burn.

7. Cut off the portion loosened at each séance: it prevents healing by its friction, and is often an annoyance to the patient.

8. Do not operate if the gland be acutely inflamed.

9. Always remember the normal shape of the tonsil; and that one must dissect much more deeply at its superior portion in order to get all of the pathologic tissue.

10. It is sometimes best to cut from below upward while taking out the inferior portion: in this convenience should be the guide.

11. By care, the operation may be rendered almost if not entirely bloodless.

12. The indication in all cases is eventual total ablation.

13. Succeeding steps on the same tonsil should not be more than ten days apart.

14. When hemorrhage occurs, stop the bleeding at once with the heated electrode, and apply a solution of silver 6 grams to water 30 c.c., or stronger.

15. Try the method, in suitable cases, and I feel confident you will concur with me in the opinion that it possesses some advantages not found in any other.

103 State Street.

DISCUSSION.

Dr. GOODALE—I have recently completed some experiments which convince me that the tonsil does absorb through intact mucous membrane. Substances in the crypts are absorbed continually, under normal conditions, into the tonsils.

Frankel, in a paper published last year, stated that he had removed inflamed tonsils without any bad results. I have also removed a large number of inflamed tonsils without harm. I think there is no objection to removing these masses of putrefying material and getting them out of the system. I think my cases have improved and recovered more rapidly than if I had not operated.

Dr. LAUTENBACH—The question of absolute and complete extirpation of the tonsil is probably the most important which will come before this Section. The method which Dr. Coulter has advocated is the best for difficult cases. An important point is to get the tonsil into position. I have an instrument which I find valuable for this purpose, especially in the cases of children. The method I usually adopt is to remove all I possibly can at one time, either by the tonsillotome, the guillotine or the scissors. The fragments can be burned out with the electro-cautery at the same sitting. I think that in this way there is less inflammatory trouble. The patient is usually willing to stand one full rather than several partial operations. This is especially true of children.

Dr. ROE—I do not advocate the use of the cautery for the removal of tonsils, for the reason that I do not regard it advisable to reduce the tonsil or to replace it by scar-tissue. On removing the tonsil with a cautery there must be a very extensive burn, leaving cicatrix behind that often causes much trouble. The plan that I have adopted on removing tonsils is first to enucleate them from all adhesions to the pillars of the fauces. This I do with a slender instrument having a curved but a blunt tip. By so doing we lessen the danger of wounding the pillars of the fauces, which is the main source of hemorrhage after tonsillotomy. After this is done I either excise the tonsil with a bistoury or remove it with a cold wire snare. By this method it is exceedingly rare that the operation is followed by any hemorrhage, and by the use of the snare it is unusual to have any hemorrhage at all. I always remove at one sitting every portion of the tonsil requiring removal. If you remove the diseased portions at different times, you have a series of sore throats, which is entirely unnecessary. There are many cases of diseased tonsils unattended with hypertrophy, which cause a great deal of disturbance in the throat. This tissue can readily be seen by pressing back the pillars of the fauces or by drawing out the diseased tissue with a tenaculum.

The importance of the removal of this diseased tissue has also been corroborated by Harrison Allen. I have seen a number of such cases in vocalists, in which very marked vocal disability was entirely relieved by the removal of this diseased tonsillary tissue. In the removal of this tissue and the use of the knife and the tonsil punch forceps is much superior to any other method, and especially to the galvanic cautery; for the reason that the cicatricial tissue caused by the use of the cautery interferes with the proper action of the pillars of the fauces, thereby causing more or less rigidity of the parts and consequently seriously affecting vocalization.

Dr. RICHARDSON—I have found that the most unsatisfactory cases were those in which the pillars of the fauces were attached to the anterior surface of the tonsil. I saw Dr. Roe operate in Rochester, and was so delighted with the procedure and with the complete separation of the pillars from the tonsil, that I obtained one of the instruments used by him. I have used the instrument since with a great deal of satisfaction, especially where there were strong adhesions between the anterior pillars and the tonsils. It is in these cases that we have the greatest difficulty and the greatest danger of hemorrhage. In the simple drawing out of the tonsil the pain is not very great and there is little or no bleeding; while we know that by the galvano-cautery method the pain is exquisite for hours and sometimes days afterward.

Dr. WOOLEN—As to the use of the cautery, I think the truth was well formulated by an assistant of mine who said: The difference between the galvano cautery and the scissors or other cold instruments is that with one we have a wound, and with the other a wound *plus* a burn, a distinction always worthy of special recognition.

Dr. DALY—There is no operation for the removal of tonsils that can not be well and efficiently done with four instruments, two knives proper length, a tenaculum, and the curved rat-tooth forceps. An enlarged tonsil is not part of a normal throat. First, remove the tonsils; second, do it quickly and effectively by the most painless method you can adopt; but last, and most important of all, leave the throat and fauces in the anatomic condition in which nature intended them to be.

Dr. CLINE—I have made liberal use of the actual cautery, and have found it valuable in certain cases. It does no harm if you use it in the proper manner. I have never had any serious results from a burn, provided I did not burn anything I had no business to. This is true also in regard to the nose. I separate the tonsils from the pillars, and then use the tonsillotome instead of dissecting out the tonsil. Unless you have the patient anesthetized, or well cocaineized, there will be difficulty in removing the tonsil by enucleation. Take the tonsil out with one stroke of the tonsillotome and then if after that there are any of the crypts left remove with the actual cautery. I see no objection to taking out an inflamed tonsil, particularly if it is hypertrophied.

Dr. GIBBONS—I approve of Dr. Roe's method of separating the pillars. In doing this I use a tonsillotome that is not sharp. I generally take a small piece of pine wood and twist it around the edge to dull it. The cold snare requires a strong hand. I have seen Bosworth find difficulty in using it. I have often thought that the snare could be improved by using hydraulic force. I use electricity very seldom, except sometimes to separate the pillars. I sometimes use the snare.

Dr. RICHARDS—The Leland tonsil knife answers very well in certain of the flat tonsils, where the ordinary tonsillotome is inadmissible. This knife, which is short, curved, probe pointed, set at right angles to the handle and made right and left, is introduced into a crypt and pushed along the curve and allowed to cut its way out. This is successively done until all the crypt are entered. The resulting tabs of tonsillar tissue are readily removed with curved scissors. Originally I followed the use of the knife with the galvano-cautery point, carrying it to the bottom of each crypt operated on. This was rather painful and followed by more or less inflammation, in one case by peritonsillar abscess, so that I now rarely use the galvano-cautery for this purpose. With this method the operation is almost painless and can be completed in one or two sittings.

THE CHAIRMAN—I have removed tonsils by all methods, and am satisfied with none of them. There is something to be said in favor of each method, and each has its disadvantages. I have adopted the expedient of selecting my cases. In those where I think hemorrhage is liable to result the cautery in some form is selected. In children the tonsillotome is the best instrument. As to Frankel's statement that he had had no bad results from the excision of acutely inflamed tonsils, I do not understand that he advises the operation in this condition. He used it as a means of securing specimens for bacteriologic investigations, not as a remedial measure.

In reference to the separation of the pillars from the tonsils, if there is any muscular substance involved, I separate it, but if there is simply mucous membrane, I do not think it is necessary to subject the patient to this additional procedure. In many cases the membrane is reflected from the anterior pillar and makes an envelope for the tonsil, it contains no muscular substance and I see no objection to making the ablation through this structure.

Dr. COULTER—I think that Dr. Goodale misapprehended my ideas in reference to the absorbent power of the tonsils.

After the removal of tonsils in an inflamed condition, you necessarily add to an already dangerous condition if you then apply the cautery. My ideas of pathology would not lead me to operate on an acutely inflamed tonsil.

The tonsil is a gland, not made up of any part of the pillars but distinct anatomically from them, and you can use the cautery without fear of producing any cicatrix. If you do not destroy any muscular tissue, you have no cicatrix. With the knife you can not do this. If you have hemorrhage, you can not see where you are operating, and will either destroy muscular tissue or leave some of the tonsil, either of which is undesirable.

A CASE OF CHRONIC ABSCESS OF THE TONGUE.

Presented to the Section on Laryngology and Otology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY C. W. RICHARDSON, M.D.

PROFESSOR OF LARYNGOLOGY AND OTOTOLOGY, COLUMBIAN UNIVERSITY.
WASHINGTON, D. C.

I offer this single case of chronic abscess of the tongue for your consideration, on account of the infrequency of its occurrence and the peculiar train of symptoms which attended its final termination. A chronic abscess of the tongue is a small rounded or oval tumor situated deep in the base on the dorsum of the tongue, anterior to the circumvallatæ papillæ, filled with pus in which fluctuation is present or absent according as the pus is, or is not, tightly pocketed and of several years' duration. According to Butlin this disease is a very uncommon one, and is most frequently observed in adults. Butlin states that the commencement is insidious, and that there is seldom any history of inflammation preceding the onset. In the case which I report I knew of the existence of the abscess for over a year before the pus was liberated or any acute symptoms developed, and the patient states that she had known of its existence since early childhood.

During the fall and winter of 1889, I was treating a young woman 18 years of age for a nasal and post-nasal catarrh. On the paternal side there was a strong tubercular history. The patient had the usual diseases incident to childhood. At the time of her first visit I noticed a prominent oval elevation in the center of the dorsum of the tongue just anterior to the circumvallatæ papillæ. This mass was about two centimeters long, about one centimeter in breadth, and projected above the surface of the dorsum of the tongue about one-half centimeter at the most elevated point. The mucous membrane over the mass was paler than over the remaining surface of the tongue and was very tense. The tumor seemed tense, deeply seated and no fluctuation could be detected. The woman stated that this mass had been noted in her tongue since early childhood, and as it had caused her no inconvenience she did not care for surgical interference. As the growth seemed in no way to interfere with functions, and offered no obstruction to the proper treatment of the throat I respected her wishes. I diagnosticated the growth to be either a dermoid or a simple cyst.

December 15, 1889, ten days after the patient had been discharged, I was called to see her on account of an intense earache. In the morning she had noticed considerable soreness in the lateral walls of the pharynx, which as the day wore on became more intense and radiated toward the ears. I examined the pharynx and found it quite normal in appearance both in the oro- and naso-pharynx. The auditory canals and membranes were normal. Hearing normal. The patient was evidently suffering, and I was perplexed.

December 16. Patient reported at my office in the morning. Had passed a sleepless night. Evidences of pain very marked. Had taken no food for twenty-four hours. Temperature 99.8. Nose, naso-pharynx, oro-pharynx, larynx, auditory canals and tympanic cavities normal. Now all the pain was referred to the ears. The growth at the base of tongue appeared about the same as usual.

December 17. Patient's appearance as she sat in waiting room gave me great concern. Her expression was one of extreme anxiety, and her face bore evidence of great suffering. The hypodermatic use of .016 gram of morphia the night before had given only a transitory relief. The organs giving rise to painful sensations all appeared as normal as ever. Temperature 100. While examining the patient's pharynx the happy idea occurred to me that the mass at the base of the tongue might be the cause of all the trouble, although appearing perfectly benign. Introducing my index finger into the mouth I essayed to make compression on the growth, when the patient gave evidences of the most intense pain. I immediately laid the abscess open through its anterior two-thirds, resulting in the evacuation of several drachms of a very offensive, thin, watery pus. The symptoms were immediately ameliorated.

December 18. The day and night's rest had worked a marvelous change in my patient. She willingly submitted to a thorough laying open of the abscess cavity, which was then thoroughly curetted and packed with iodoform gauze. From this date the patient made a rapid and complete recovery. Swelling disappeared, and at the present writing shows only as a slightly elevated linear cicatrix. The patient is now under my observation, and the cicatrix is all that shows of the former condition.

The most interesting feature of this condition is the fact that the abscess remained quiescent so many years and then took an active course. It is also interesting to observe that all the symptoms produced by this change in the nature of the abscess were referred away from the seat of the disease. There was no change in the appearance of the tissues over or about the seat of the abscess, nor was there any spontaneous or superficial pain in the part of the tongue affected. It was only when firm and great pressure was made that any evidences of pain were demonstrated.

1102 L. Street, N. W.

DISCUSSION.

Dr. WOOLEN—Possibly this case was not an abscess for all these years. I have a case of blood cyst, or perhaps more properly varix of the tongue, which I have watched with solicitude for many years for fear it would rupture. Possibly Dr. Richardson's case may have begun in that way. I can hardly understand how an abscess could exist for so many years and pus be carried in it all that time. I think it likely that there was degeneration of some cystic formation. In my patient the growth is bluish in appearance, has evidently liquid contents, and is the size and shape of a teaspoon inverted on the tongue. It is pulpy and fluctuates as blood fluctuates. It gives the patient no inconvenience, but I fear rupture either spontaneously or artificially.

Dr. W. H. BRYAN—I can hardly conceive of an abscess existing as such for so long a time. It is possible that there may have been a cystic condition from which has developed a septic inflammation at a later interval.

Dr. D. BRADEN KYLE—I have only seen one case of abscess of the tongue and that was tubercular. Not only the tonsil but the cervical glands were involved, although the glands did not suppurate. Six weeks before operation marked symptoms of abscess at the base of the tongue had developed. The abscess was opened and contained cheesy material in which tubercle bacilli were found. This was a so-called chronic abscess, but it was really an acute condition at the time it was opened.

Dr. MAX THORNER—I have seen two cases of chronic abscess of the tongue. One was produced by a foreign body. There was swelling and all the symptoms of abscess at the base of the tongue. The symptoms had been present for half a year. I found a fish-bone embedded in the abscess. In the second case there was a chronic abscess of the base of the tongue of ten months' standing, which was no doubt tubercular. There was great difficulty in healing the wound, which closed superficially leaving a fistulous opening. I could get no detailed account of the history.

Dr. C. W. RICHARDSON—I had also thought at first that my case was probably a broken down cyst that had undergone suppuration, but after looking up the subject I came to the conclusion that it was a chronic abscess, for several reasons. Cysts are usually situated where the glands are more prominent and more numerous. They are more on the surface than this, which was embedded in the tongue, or to use Dr. Woolen's description, looked as though a teaspoon had been placed on the surface of the tongue. I am ready to accept the diagnosis that the condition may have been tubercular. In fact this young woman has a strong tubercular history on the paternal side. Nevertheless I think there is such a thing as chronic abscess of the tongue, and that such cases have been described, among them some which have existed for years before being opened.

CASE OF RECURRENT HEADACHE, EACH ATTACK BEING RELIEVED BY THE DISCHARGE THROUGH RIGHT NOSTRIL OF A FLUID FROM THE CRANIAL CAVITY.

Presented to the Section on Laryngology and Otology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY W. SCHEPPEGRELL, A.M., M.D.

NEW ORLEANS, LA.

The case which I report is so unusual that I am unable to find a similar instance in the records of medical literature. The case is one of recurrent headaches of a most violent character, each paroxysm continuing until relieved by the discharge of a watery fluid from the right nostril.

The following is the interesting history of this case: Sister M. J., a member of a holy order, suffering from deafness and an affection of the throat, was referred to me in January, 1893. While treating these conditions, from which the patient soon recovered, she called my attention to the repeated headaches from which she suffered, and to the fact that they were relieved by the discharge of a straw-colored fluid from the nostrils.

In February, 1885, the patient suffered from a most agonizing headache, which persisted in spite of the efforts of several physicians. The pain at times became so severe that the patient was entirely oblivious of her surroundings. This continued for three weeks, and was relieved by an accident which appeared almost providential. While descending a stair, the patient fell down a considerable distance, her head striking against a stone jar at the bottom of the staircase. The fall was so severe that the patient was unconscious for several seconds, but when she revived, she observed that there had been a profuse discharge

of a yellow watery fluid from the nostrils, and that the headache, which had persisted for three weeks, had entirely disappeared.

Five or six weeks after this occurrence the headache developed again, the symptoms being the same as in the former attack, but at the end of the fourth day there was a spontaneous discharge from the nostrils, principally from the right side, and again complete relief. These attacks recurred at varying intervals, the intermissions sometimes being only twenty-four hours, and rarely more than two weeks. The headaches persisted from three to five days, and sometimes as long as ten days.

Various remedies were prescribed for the relief of the patient, but without success. The discharge of the watery fluid from the nostrils, at the end of the attacks, did not appear to have attracted the attention of the attending physicians, or if it did, was considered as a mere coincidence.

On account of the unsuccessful efforts to relieve this condition, the patient finally decided to make no further attempts to relieve this affection, which made her life a burden.

In describing her symptoms to me, the patient stated that when these headaches commenced there was a feeling of stiffness in the neck near the collar bone; then the pain seemed to ascend until it formed a focus in the upper part of the head near the crown, and produced a sensation as if a boil were forming, the pain extending over the whole upper part of the head, and her eyes could be kept open only with difficulty. The face is flushed, but there is no elevation of temperature. An ophthalmoscopic examination gave negative results, and there was no exophthalmus.

From a careful study of this case, the conclusion was evident that there was direct cause and effect between the watery fluid, which afterward discharged from the nostril, and the recurrent headaches. The quantity of liquid discharged (about one ounce) indicated that an accumulation formed in a receptacle of about this capacity, and that the pressure was instrumental in causing the violent pain, and that relief was due to the discharge of the fluid.

From the location of the pain, my first impression was that the sphenoidal cavity of the right side was the cause of the symptoms complained of, and when I explained my view to the patient, she readily gave her consent to an exploratory puncture into this cavity, with a view of obtaining relief.

The opening of the sphenoidal cavity, as well as the other operative procedures, were undertaken during a paroxysm of headache, while there was evidence of strong pressure, so that liberation of the fluid and the subsequent relief would show that the seat of the trouble had been reached.

After thorough cocaineization of the right nasal cavity, a long trocar, with the point slightly bent upward, was passed close to the septum at the level of the middle turbinal and then directed upward in the posterior upper part of the nasal cavity. With some pressure and a slight rotary motion, the wall was perforated and the free entrance of the trocar showed that the sphenoidal cavity had been reached. The trocar was then withdrawn and the canula left in place, but there was no discharge of the liquid.

A probe was now passed into the cavity, which appeared to be normal. There was no discharge of fluid, and the patient experienced no relief from the headache. The operation was done with due regard

to asepsis, and there was no reaction or ill effects.

As there was considerable pressure about the eye, and from the fact that pain is sometimes referred to another locality by the patient, I then decided to open the frontal sinus. After an ineffectual attempt to catheterize this cavity from the nostril, the frontal sinus was opened externally under chloroform. A vertical incision was made over the inner superciliary region of the right eye, the skin and periosteum drawn back and an opening through the outer wall of the sinus was effected by means of a small trephine. There was no discharge of a fluid.

A probe passed through this opening entered the nasal cavity without difficulty. The periosteum and skin were then carefully stitched, and the wound healed by first intention. The scar was scarcely noticeable, but there was no relief from the headaches.

Although an affection of the ethmoidal cells could not readily explain the symptoms, still in view of the intense suffering of the patient, and her almost total disability to perform her duties, every attempt was made to relieve her. The ethmoidal cells were opened without success, and the antrum of Highmore was catheterized without giving relief.

While making a preliminary report of this case before the Orleans Parish Medical Society, a physician, in the discussion, stated his opinion that the symptoms might be of hysterical origin, and that there was no evidence, besides the word of the patient, that there was a discharge from the nostrils at the end of each paroxysm of headache.

Though this opinion was contrary to my belief, I decided to obtain corroborative evidence, and had the patient, during one of the attacks, placed in a private ward of the Eye, Ear, Nose and Throat Hospital, under the charge of two trained nurses, who were instructed never to leave the patient and to watch carefully for the discharge of the watery fluid from the nostrils.

At the end of three days the watery discharge was seen by the nurse, and a portion of it saturated a towel on the bed.

Having now excluded the various accessory sinuses, the probability of this discharge coming from the cranial cavity, which occurred to me from the early history of the case, became more fixed, and I decided to obtain a specimen of the discharge for microscopic examination. With this view, the patient was instructed to have a vessel always with her during the next paroxysm and, if possible, to catch the fluid so that a careful examination could be made.

The second attempt was successful, the larger part of the liquid being discharged into a bowl and soon after brought to me.

The fluid had a specific gravity of 1005, was slightly alkaline in reaction and contained a small amount of albumin. Chemically, the liquid resembled the cerebro-spinal fluid and the contents of the cranial lymphatic vessels in this region, which are almost identical in character. When this fluid was allowed to settle in a conical glass, there was a heavy white deposit; the clear supernatant fluid was of a pale straw color, and did not coagulate. The sediment consisted almost entirely of pavement epithelial cells, some occurring singly and others in flakes. A few red blood corpuscles were seen.

In a second specimen sent for examination, the admixture of blood was so large that it imparted a reddish tinge to the whole body of the liquid. In

this specimen, also, there was a heavy deposit of pavement epithelium or endothelium.

It has been shown by T. S. Flatau (*Deutsche Med. Woch.*, Leipzig, Oct. 30, 1891) that there is sometimes a communication between the subarachnoid space and the nostrils, and he quotes a case of hydrocephalus which recovered after an abundant serous discharge from the nose. The existence of such a communication is also demonstrated by Schwalbe, Key and Retzius. Naunyn and Schrieber were also able to inject warm salty solution into the subarachnoid space of the dog which was discharged at the nostrils, the phenomena being accompanied by a protrusion of the eye and chemosis. In investigations on the human subject, Flatau found that although injections into the subarachnoid space reached the nose, the injection of colored fluid into the nose did not lead to an entrance of the fluid into the arachnoid space on account of the barrier presented by the columnar epithelium.

Another case, which is interesting in this connection, is one of meningo-encephalitis consecutive to an exploration of a supposed frontal sinus, reported by Dr. Mermod (*Ann. des Mal. du Lar. et de l'Or.*, April, 1896). The following is a synopsis of the report of this interesting case: A man, 30 years of age, who had undergone the successive opening of the right maxillary, the left sphenoid sinus, and of the right anterior and middle ethmoidal cells, on account of a chronic suppuration of these cavities, was affected with a cephalalgia of the right frontal region, which diminished after a free evacuation of a clear nonpurulent liquid. Under the supposition that it was an affection of the right frontal sinus, a flexible shaft was introduced, which penetrated a large cavity resembling an enlarged frontal sinus.

A second exploration, made under the same conditions, to the depth of $6\frac{1}{2}$ cm., measured from the entrance of the nostril, was followed by violent pain in the head, rigors and unequivocal signs of meningitis. A large trepanation was then made, and it was found that the frontal sinus was entirely wanting, and its place was occupied by the frontal lobes. A sound introduced from above immediately and without difficulty penetrated into the nostril.

The patient died twenty-four hours later. The autopsy showed a sero-purulent meningitis commencing from the anterior part of the frontal lobes; there was no traumatism of the brain. Although the exploration had been made with care, and under all necessary antiseptic precautions, it had been the cause of the meningitis. The liquid, which ran intermittently from the nose, had been a cerebro-spinal fluid.

From a careful analysis of the case which I have reported, I concluded that the fluid, which had caused the first attack of cephalalgia, had accumulated in the cranial cavity, and that the fall had been instrumental in breaking though the barrier which existed between the liquid and the nasal cavity.

The point of differentiation, which now presented itself, was as to whether this fluid came directly from the subarachnoid space or from some cystic formation in this region, connected with the lymphatic circulation.

The subarachnoid space is the interval between the arachnoid membrane and the pia mater. At the base of the brain there is a wide interval between the two middle lobes, and also behind the hemispheres of the

cerebellum and the medulla oblongata. This space is filled with a cerebro-spinal fluid, which fills up the interval between the arachnoid space and the pia mater. The subarachnoid space usually communicates with the general ventricular cavity of the brain by means of an opening into the inferior boundary of the fourth ventricle.

The conformation of this space and the extensive communication of its fluid, including even the ventricular cavities of the brain, would easily explain the depressing as well as agouizing character of these headaches, the effects of which were so severe that they almost entirely incapacitated the patient from duty.

If this fluid were discharged from the subarachnoid space, it was difficult to understand why the same quantity came from the nostrils after each attack, and also why the discharge ceased so abruptly and did not continue to drip for some time after the first pressure had been relieved.

This peculiarity caused me to believe that it was due to a cyst connected with the lymphatic circulation in this region. The foramen cecum is an aperture formed by the frontal bone and the crista galli of the ethmoid, and when pervious transmits a small vein from the nose to the superior longitudinal sinus. If the efferent lymphatic vessel of the perivascular lymphatics surrounding this vein should become occluded, it would form a lymphangiectasis, which would continually dilate from the plasma oozing from the blood vessel surrounded by these lymphatics.

The location of such a cyst in this region would not only cause all the disturbances due to pressure in the subarachnoid space, but would also explain the limited amount of fluid which was discharged after each attack. The slight admixture of blood corpuscles evidently came from the ruptured point in the upper part of the nasal cavity.

When my conclusions had been formed in this case I declined to make further surgical interference. Learning that the patient had suffered from attacks of rheumatism, I suggested to her physician to push the anti-rheumatic preparations, which was done, however, without any beneficial influence on the recurrent headaches.

I have from time to time examined the nostrils of this patient to see whether, perhaps, the cyst might protrude into the nostril, as we know that continued pressure will sometimes cause absorption of even bony tissue, and that the attacks might be relieved by early incision, but this has not yet been the case.

Medical Building.

DISCUSSION.

Dr. GIBBONS—I am following at present a peculiar case of headache. Among the symptoms I find a suicidal tendency and also a fear of going insane. I think it is really a disease which ought to be termed "suicide," differing from melancholia in that really insane persons do not think they are insane, whereas these patients will tell you that they contemplate insanity or suicide.

The physiologic functions of this region are not well known. In my opinion, the cells have something to do with receiving from the air an electric current. They are grouped exactly like the cells of a storage battery, and I believe they have some such function. If Dr. Scheppegrell does not get relief after these operations, I believe it is because the enlargement of the cells or some other growth has not yet been reached.

Dr. J. SOLIS-COHEN—I would like to ask whether the possibility of specific disease has been eliminated.

Dr. SHEPPEGRELL—The attending physician had given iodid of potassium without effect.

Dr. J. H. BRYAN—Possibly it may be one of hydrops. Secretion may have taken place in one the deeper ethmoidal cells

which could not be opened. Hydrops is a very rare condition. I thought it did not exist until Dr. Herman Knapp made his interesting report of some cases, the history of one of which was very much like this.

Dr. MAX THORNER—There seems to be no doubt that the headaches were due to some intracranial pressure, though the ophthalmoscopic examination showed nothing unusual. In a case shown by Dr. Woakes in 1885 at the London Hospital for Diseases of the Throat and Chest, he considered the discharge from the nose to be cerebrospinal fluid, in a case that bore close resemblance to the one reported. A chemic and microscopic examination, if I remember rightly, was not made at the time. The discharge occurred intermittently and was always preceded by headache. A communication between the arachnoid space and the lymphatics of the nose has been proved to exist by Flatau's magnificent demonstrations, made at the International Medical Congress at Berlin, in 1890. This fact accounts for many otherwise obscure phenomena.

Dr. J. A. STUCKY—From the history of the case and the quantity of the discharge, I am almost forced to conclude that the discharge was from the cranial cavity. There would not be over an ounce or so from the ethmoidal cells, even if they were much enlarged.

Dr. G. V. WOOLEN—I have often been surprised at the amount of discharge in the ethmoidal cells and at the large quantity of polypi that can be taken from this region. The amount of operative tolerance in this locality is remarkable at times. It does not seem that the fluid was cerebro-spinal, or there would have been other cerebral symptoms besides pain, such as coma, paralysis, etc.

Dr. A. DE VILBISS—Although many have done considerable work in the region of the roof of the nose, we should not invade that region without some fear of doing harm. Only about four months ago I witnessed the death of a patient from an operation in that direction. In old cases where we have empyema we can operate more readily than in acute cases. That the cerebro-spinal fluid can leak out and escape through the nasal cavity I believe, though I have never made any postmortem demonstration of the avenues by which it comes. I had a patient who, every few months, by bending the head forward could discharge about half a teaspoonful of cerebro-spinal fluid through the nose. He had also symptoms of focal epilepsy. He was relieved by puncturing the dura and drawing off the cerebro spinal fluid.

Dr. SCHEPPEGRELL—This case could not be one of hydrops of the ethmoidal cells, as this would not account for the sudden and complete discharge of the fluid, which indicates the existence of a kind of buffer, which in this region could be furnished only by the intracranial pressure. As already stated, a cystic accumulation in the subarachnoid space would alone explain the character of the fluid examined and the various symptoms presented in this case.

THE TREATMENT OF EMPYEMA OF THE FRONTAL SINUS.

Discussion in the Section on Laryngology and Otology, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

OPENED BY J. H. BRYAN, M.D.

WASHINGTON, D. C.

In accepting your invitation to open the discussion on this most important and interesting subject, I feel that I can not do better than first to call your attention to a few of the anatomic peculiarities of the frontal sinuses, in order that the pathology and treatment of chronic suppurative inflammations of these cavities can be the better understood.

The size of the frontal sinuses varies greatly in different subjects, and frequently in the same subject the variation is very marked, one cavity occasionally being quite large while the other is many times smaller, or absent altogether.

After an examination of 120 skulls made by Herbert Tilley¹ he considers a sinus normal when it measures 28 mm. from the median line outward to about the junction of the inner and middle third of the supra-orbital ridge; and in vertical extent measured from the root of the nose from 20 to 22 mm. Lamb,² who

has also investigated the size of these cavities, found the right one with a varying capacity from one and one-third to six c.c. while that of the left sinus was from one and one-fourth to four and two-thirds c.c. As showing the difference existing between the two sides he found in one instance the left sinus was to the right as seventy to ninety-five.

In health these cavities are separated by a very thin partition or septum which in the majority of instances is complete, although they occasionally communicate through a small opening. The septum is occasionally not straight, deviating to one side or the other thereby rendering one cavity smaller than the other.

Situated between the frontal and ethmoidal sinuses there is a series of cells formed by the junction of the ethmoid and frontal bones, but which form no part of either of these cavities. They, however, bear a very important relation to both sinuses, for when affected by an extension of a morbid process in either of the adjoining cavities they seriously complicate these conditions and render the prognosis much more uncertain. I believe in nearly all severe cases of empyema of either the frontal or ethmoidal cavities these cells are to a greater or less degree, affected.

Chronic empyema of the frontal sinuses while not an uncommon occurrence in some of the continental countries, as Russia and Germany, has not been so frequently observed in this country until within the past few years, and especially since the frequent visitations of epidemic influenza, which seems to have a special predilection for the accessory sinuses. While chronic suppuration of this cavity may and does frequently arise from other causes such as an extension of simple catarrhal inflammations from the nasal cavities, and from the retention of the secretions in the sinus by obstructive lesions within the nose, the most frequent cause in my experience has been the extension of the morbid process from the nose in the course of an attack of grippe.

While the prognosis of this affection is generally favorable the treatment will be found to be difficult and tedious according to the methods adopted for its relief.

Since the rapid advances made in the study of diseases of the nose there is a tendency on the part of some rhinologists to treat this affection through the nose, especially since Jurasz has pointed out the feasibility in a few cases of passing a probe through the infundibular orifice in the nose. There is no doubt that in a few instances this can be done, but in the majority of cases it will be found to be impossible to pass a probe into the frontal sinus through the fronto-nasal duct, for generally this duct is situated far back, and is occasionally so tortuous that no probe can be made to follow its course. When sounding the frontal sinus is possible treatment conducted through the nose without first making an external opening is only suitable for acute cases.

Max Schaeffer has proposed opening the sinus by making a forced opening through the nose. It is only necessary to mention this method to condemn it as very dangerous, for there is already one fatal case, by this method, on record. Any one who has paid any attention to the anatomic irregularities that exist in this region can not feel assured that he can enter the sinus by forcing an instrument through the middle meatus or middle turbinated body. Even should one be successful in entering the sinus by either of the above mentioned methods little could be

accomplished in relieving the inflammation, for in these chronic cases the pus is very thick, best described as stringy in character; the cavity is generally filled with granulation or polypoid tissue, and there is frequently some caries of the surrounding bony walls. When such conditions exist no amount of irrigation with antiseptic lotions will relieve the inflammation. I can therefore speak of these intranasal methods only to advise against their employment in chronic frontal sinusitis of long standing. I think most authorities of any extended experience will agree that one of the external methods will in the majority of cases be called for, and the earlier the operation is done the shorter will the usual subsequent treatment be.

There are several methods proposed for entering the frontal sinus. One, which I employed in a case successfully, but in which the subsequent treatment was very tedious, is where the incision is made along the lower border of the supra-orbital ridge, first pulling the integument forcibly up on the forehead so that the line of incision would fall just under the eye-brow. The incision beginning at the root of the nose and extending outward from an inch to an inch and a half is made down to the bone, the integument and periosteum elevated, and the sinus opened at the internal angle either by means of a drill, chisel or trephine. This opening does not admit of a thorough inspection of the interior of the cavity, and any caries of the septum or fronto-ethmoidal cells could easily escape detection. The disadvantages of this method are that the opening does not admit enlargement of the fronto-nasal duct as readily as that through the anterior wall, consequently the cavity has to be irrigated through a rubber or metallic drainage tube introduced into the sinus at this point, which results in the patient recovering with a decided depression over the opening into the sinus, and occasionally with a fistulous opening remaining.

Panas,³ who has had a large experience in treating this affection, recommends that an incision be made along the lower border of the supra-orbital ridge and then makes another perpendicular to this upon the base of the nose, the triangular flap including integument and periosteum thus formed is detached from the bone, and an opening made into the sinus near the inner angle of the orbit large enough to admit of a thorough exploration of the cavity.

Another method, which offers many advantages over the above mentioned procedures, is that devised by Ogston⁴ of Aberdeen, in 1884, and more recently and independently advocated by Luc.⁵ In this operation the incision is made in the median line commencing at the root of the nose and extending from an inch and a half to two inches on the forehead. The skin and periosteum are elevated and a centimeter of bone removed from the anterior wall of the sinus by means of a crown trephine applied several lines from the median line and about two or three lines above the supra-orbital ridge. By this means an opening of sufficient size is made so as to admit of a thorough exploration of the sinus, and caries of the bony walls, the septum, or of the fronto-ethmoidal cells can be easily detected and removed. After the removal of any polypoid or necrotic tissue the cavity is thoroughly cleansed, and the fronto-nasal duct enlarged by passing a trocar from the sinus into the nose, using the little finger as a guide, after which a self-retaining drainage tube is introduced through this enlarged

opening and allowed to remain as long as necessary. The membrane lining the cavity may be touched with a 20 per cent. solution of the chlorid of zinc and the wound closed by means of an interrupted or a subcutaneous suture, which should then be hermetically sealed with a solution of iodoform and collodion. The subsequent irrigations can be made through the drainage tube until all secretions have ceased to form.

The advantages of this method of treating chronic abscesses of the frontal sinus are manifest in that the cavity with all of its irregularities is rendered thoroughly accessible, and all diseased tissue can be removed before closing the wound. There is no depression left after the removal of the button of bone from the anterior wall of the sinus, and only a slight scar remains which in carefully managed cases amounts to little more than an exaggeration of the natural cleavage of the skin so frequently observed in this region.

The duration of treatment is very materially reduced by this method. In a case I reported at the recent meeting of the American Laryngological Association the duration of treatment was a little over six weeks from the date of the operation, and it was somewhat prolonged in this case owing to an unfortunate accident which resulted in suppuration taking place in the line of incision, either from an imperfectly sterilized cat-gut suture, or an infection of the under surface of the wound from the cavity below.

Botey⁶ has modified this operation somewhat with the view of preventing the scar that may be left after the median operation. After shaving the inner two-thirds of both eyebrows, he makes an incision the length of the internal third of the supra-orbital ridge, which is prolonged to the root of the nose. After elevating the integument and periosteum he removes the external plate of the sinus near the root of the nose, and then carefully detaches fragments of the anterior ethmoid cells until a large communication is left between the frontal and nasal cavities; the sinus is cleared of all diseased tissue and a strip of iodoform gauze introduced through the opening into the nose, when the external wound is closed.

This operation would seem to present some advantages over that of the Ogston-Luc method, especially in not leaving much of scar, and also in having the fronto-nasal opening sufficiently large to do away with a drainage tube.

After the artificial opening has been made the subsequent treatment consists in keeping the cavity free from all secretions, which is done by frequent irrigations with antiseptic lotions. The use of strong antiseptics in this cavity as well as in the other accessory sinuses can not be too strongly condemned. The best results are obtained after the persistent use of such mild applications as hydrogen dioxid and a saturated boric acid solution.

Dr. MAX THORNER—Diseases of the frontal sinus, acute as well as chronic, are often of such a nature that diagnosis is easy, but in some cases it is very difficult. It is often extremely hard to find from which of the accessory cavities the discharge takes place. A patient who was brought to my service in the Cincinnati Hospital had previously all the accessory cavities of one side opened without finding the

cause of persistent headache. It had been rather the habit of late to operate on the accessory cavities in headache which can not be traced to any other cause. It is almost impossible to gain admission into the frontal sinus through the nose, although I will not deny that it can occasionally be done. Some time ago I tried, on the cadaver, to introduce probes through the nose into the frontal sinus, and was astonished to find in how many different directions my probe had been conducted. Some observers have repeatedly stated that it was very easy to introduce a probe or flexible canula, but I do not think so. Even if there is only one case on record where death has followed the attempt at opening the frontal sinus from the nose others have occurred. Whatever may be the opinion regarding acute, I think that all agree that in chronic cases we should do the external operation. Operative treatment through the nose in such cases is almost impossible, and always dangerous.

The method mentioned by Dr. Bryan is among those almost universally used. Of late I have changed my method slightly. I do not make the incision in a straight line along the eyebrow, but following the eyebrow about two-thirds its length, and then curve it slightly upward toward the median line. I have found that access to the cavity is better, while the scar is almost invisible. In chronic cases, where there is extensive caries it is almost impossible, in my experience, to get healing in four to six weeks. In the modern, or so-called radical operation upon the middle ear cavities, we have the advantage that we plaster the skin into the wound-cavity to cover the raw bone surfaces, but we can not do that in the frontal sinus, though I think it has been proposed. Healing takes almost twice as long where there is extensive caries, especially where the conditions for drainage are not favorable. I have found it most advantageous in such cases to drain for some time at least through the external opening although it takes longer. In all cases where I found extensive caries, I left a little hole for drainage, and the results were better than where I had closed the external wound by sutures at the time of the operation and depended upon drainage through the nose alone. This method does not preclude closing the external wound at once in cases where we find no caries at all, or only to a slight extent.

Dr. J. A. STUCKY—I have seen quite a number of these cases, and in every one there has been serious trouble in the middle meatus, and the middle turbinal has been enlarged. I have found that removal of the anterior end of the middle turbinal gave great relief. I believe the orifice of the infundibulum is closed by adhesions, and if we succeed in opening the process and subduing the inflammatory conditions, nature will often complete the case. By frequent cleansing of the nasal cavity and keeping the patient quiet, especially in acute cases, we can prevent more serious attacks. As to chronic cases, I am in favor of the external operation. I believe in making a large opening to see what you are doing and also to get free drainage. I prefer to make the opening with the trephine, at the root of the nose. I do not like the opening at the eyebrow, which I have tried but have had much trouble and swelling.

Dr. SCHEPPEGRELL—Where the external operation is necessary it should be done by the radical method which Dr. Bryan suggests. We should not however proceed to external operation too soon. The attempt at intranasal treatment should be made first. As to

the difficulty of entering the frontal sinus through the nose, I have done it a great many times, and have been sure that the probe reached the cavity. If the case has not gone to the point of caries, we should try the intranasal treatment first.

Dr. DEVILBISS—I am in favor of the external opening. I would like to ask the last speaker to give us his plan for draining the frontal sinus through the nose where there is empyema.

Dr. SCHEPPEGRELL—I have used a weak solution of peroxid of hydrogen to clear the nostril. No two cases are alike, and we must study the topography of each individual case. I try until I finally succeed in finding the natural channel, and then the probe is passed upward into the passage, then syringe with a gentle and continuous pressure.

Dr. COBB—The difficulty of catheterizing these cases is almost unsurmountable. In experimenting upon anatomic preparations, if you take a probe and bend it to the extent necessary to reach the frontal sinus, you will find that the bend is too great to allow it to enter the nose. The evidence is lacking that the probe really does reach the sinus. The fact that pus follows it would prove only that the ethmoidal cells might be affected. Peroxid would cause bubbling in case it encountered any pus on its way to the frontal sinus. It is very difficult to tell whether you are actually in the sinus.

Dr. FREUDENTHAL—I always try to benefit those chronic cases by intranasal treatment, but I have never succeeded, and finally have to come back to the external operation. I have one case on record which I have been treating for three years. I do not believe that entrance into the frontal sinus is as difficult as some of the gentleman believe. In about 15 or 20 per cent. of the cases with a very fine probe, you can enter the sinus easily.

Dr. MYLES—I have operated on eleven cases externally, and dozens internally as I suppose all have. I originated the idea of taking out all of the bone between the central part of the nasal processes and the sinus, as near the floor as possible. I operated on several cases in that way, and kept them open for six weeks. These cases are all in fairly good shape with freedom from pain, though occasionally a little mucopus escapes. I abandoned this operation because I could not chisel away the floor of the sinus through this opening and it was difficult to enlarge the opening to the extent that I wished. So I adopted the method of Luc, I believe. I think his technique is by far the best of all. A few weeks ago I operated on two cases in which the cavities were full of pus and carious bone. I chiseled a large hole just above the orbital ridge, making a passage into the nose. In both cases I used soft rubber tubes and sewed up the external wound at once. I left the tubes in for about three weeks. The patients were relieved, and the one which was the more serious is now doing well. The other operated on after a general surgeon had done a double external operation, and I had to cut through a line of cicatricial tissue. The external wound was perpendicular, and healed in three days. The secret of success is in making a large opening into the nose. I am strongly in favor of removing the middle turbinal before operation and also the ethmoid bone which lies between the infundibulum and the upper part of the septum.

As to immediate closure of the external wound, the new membrane forms just as well in the closed dark

cavity as in the light. I have tried to ascertain how the bare bone closed over in these cavities. In one case I reopened, and found the granulations very exuberant and softened by the atmosphere which passed upward in respiration.

THE CHAIRMAN—We must draw a sharp line of distinction between acute and chronic cases. Our reports and statistics are vitiated by dragging in acute with chronic cases. The majority of acute cases recover spontaneously, and the operation receives the credit of the cure. Intranasal methods should be carried out tentatively, especially where there is polypoid degeneration of the middle turbinal or the presence of actual polypi. The nose should be cleared and the anterior end of the turbinal removed if necessary. The operation by the intranasal method often does not result in a perfect cure, though it often relieves the headache and may establish better drainage. Intranasal treatment should not be carried on too long; in this way we may weary and discourage our patients. After having done what is really essential by intranasal treatment we should proceed to the external operation. I consider Luc's a great advance over previous methods in the external treatment of this disease. It will enable us to promise a cure if there is no caries, and it leaves no deformity. This operation has been well described by Dr. Bryan, but there are several points that were not quite clear to me. First, as to whether the incision is made exactly in the median line or deviated a little to one side; second, in reference to the modification of Luc's operation, in which there is an incision along the orbital arch and then a vertical one connected with it, with a view to lessening the deformity.

Dr. BRYAN—I invariably relieve the intranasal conditions as far as possible before resorting to operation. The removal of the middle turbinated body is sometimes necessary when the ethmoidal cells are involved. These cases can not be cured unless every bit of caries and pus is removed. After the cavity has been thoroughly curetted and the diseased tissue removed, I know of no reason why the patient should have an open wound until the so-called healing of the internal cavity takes place: this occurs just as rapidly when the wound is closed. As to the incision, my last case had a decided furrow in the median line and I followed this. It seems to me that Botey's method is a great advance over the median operation, though I have never tried it. The incision is described as commencing at the inner third and under surface of one eyebrow and then carried across the root of the nose, the integument and periosteum elevated, and the opening made just above the inner angle. The great advantage is that the rubber drainage tube is dispensed with. The communication between the sinus and the nose is a large one.

Gerson's Elastic Suspensory Bandage.—A soft elastic cloth, fringed on one edge, is covered with "York's rubber zinc plaster" and applied in epididymitis as follows: The scrotum is freed from hair and moisture and the bandage is applied around the empty scrotum below the testes, with the fringe up to prevent cutting. The scrotal skin thus drawn tight exerts constant pressure on the swollen testes and reduces the swelling. When the bandage becomes loose, as the swelling subsides, it is removed and applied higher up until complete recovery. In case of varicocele the bandage is removed at night. Frank and Lassar endorsed from personal experience the usefulness of this bandage.

MENIERE'S DISEASE, WITH REPORT OF A CASE.

Presented in the Section on Laryngology and Otology at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JAMES M. BROWN, M.D.

Instructor in Otology in the University of Pennsylvania; Assistant Aural Surgeon to the Hospital of the University of Pennsylvania; Aural and Ophthalmic Surgeon to the Western Temporary Home; Aurist to the Presbyterian Orphanage.

AND JUDSON DALAND, M.D.

Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania; Assistant Physician to the Hospital of the University of Pennsylvania; Professor of Clinical Medicine in the Philadelphia Polyclinic.
PHILADELPHIA, PA.

The employment of a term as indefinite as "Meniere's Disease" is now generally held to be, in giving title to the subject to which I ask your attention, may call for some explanation or apology, for quoting the words of Sir Wm. B. Dalby: "The term serves more frequently to mark ignorance of the lesion which occasions a series of symptoms, often analogous, but which are under the influence of very different causes." Such apology if called for must be the admitted absence of any designation more definite, and yet generally applicable to all cases of, or the various symptoms met with in this disease, together with the great diversity of opinion which still obtains in the minds of the profession concerning it. Until we know the exact pathology and are able to separate other analogous diseases with which it may be confounded, it is wiser to hold to the name "Meniere's disease." Faintness, deafness and vertigo were the symptoms that especially engrossed Meniere's attention, and of these the latter seemed most momentous, and his investigations led him to believe that the lesions which produced it were restricted to the semi-circular canals. That this is not the universally accepted opinion is proven by the widely divergent expressions of master minds engaged in the study of both its lesions and symptoms. Politzer and Lucae both report instances in which the semi-circular canals were absent or, by trauma, filled with blood, and yet the patients did not suffer from any disturbance of equilibrium. Gradenigo, Moos and Burnett believe the vertigo to be chiefly due to an extension to the labyrinth of a chronic catarrhal affection of the middle ear. Steiner of Cologne believes that the vertiginous symptoms result from lesions within the brain or its membranes, causing alterations in pressure. Baginsky, Randall, Dench and others regard Meniere's disease as a complex of symptoms, in which the cause can not be due to disease of the canals alone, but whether labyrinthine involvement, such as hemorrhage or serous effusion, is present in all cases is a question, as yet, not certainly answered. It may be caused by organic changes in the perceptive mechanism, or secondary to diseases of the conductive apparatus, or to blood conditions, or circulatory disturbances, to certain diatheses, or may be wholly reflex. Mettler says it is too complicated to be considered as a mere disarrangement of the function of the semi-circular canals alone, and yet it may be considered that in true Meniere's disease these only are affected, and that aural vertigo may not be aural at all, except so far as having certain aural symptoms associated with the vertigo are concerned. Bezold has collected and reports forty-six cases of necrosis of the labyrinth, and notes that only twelve showed symptoms of vertigo.

Mackenzie says it is due to the effect of irritation of the terminations of the vestibular nerve. Finally, aural vertigo may co-exist with or occur apparently as the result of the most varied diseases, as for instance, hysteria, hystero-epilepsy, syphilis, vaso-motor disturbances, cerebral diseases, inflammatory conditions of the middle ear or growths upon the auditory nerve, gouty or rheumatic diatheses, pelvic and visceral inflammations, etc. And so I might multiply authors and recount opinions and cases, but enough has been given to show that we are dealing with an intricate and imperfectly understood disease, one whose manifestations seem entirely out of proportion to its lesions.

The following case is so typical that I believe its relation will be of special interest. The subject of it, Mrs. S., age 30, married, the mother of two children, the youngest born just one month prior to the commencement of the present illness. Her accouchement was normal and convalescence good. Family history excellent, with the exception of one brother who died at 33 of cerebral meningitis. She has always enjoyed good health, and is of a most bright and cheerful disposition, courageous and hopeful to the extent of light heartedness throughout her most distressing sickness. Manifesting a most intelligent interest in her own case, so apt in noting and describing her various symptoms or recounting her sensations, I requested her to write them out for me, and after hearing them, I think you will agree with me that a study from the standpoint of patient or laity, is not only an innovation but one of value and instruction:

"I went to bed on the night of January 6 feeling well but extremely tired, and the first premonition of approaching illness was on being awakened at 8 o'clock in the morning of the 7th, when I experienced the most violent noises in my head, like the pounding of iron. I had no dizziness or nausea during the forenoon, but on going down stairs received a slight physical shock as if the steps wavered, and came in contact with the feet too suddenly. This continued all the morning, and was accompanied by a feeling of great lassitude. I ate heartily at luncheon, had no pain in my head or elsewhere, although the noises continued without interruption, if anything, increasing in violence. A loud noise such as the water rushing in the toilet room, seemed to aggravate this condition, filling the head with noise. At about 1:30 p. m. I was seized with the acute attack of vertigo. I had just nursed my month-old baby when the room suddenly and with great violence seemed to turn directly upside-down, the floor approaching me and giving the sensation of an actual shock as if caused by an earthquake. I staggered to the door with my feet wide apart like an intoxicated person and called for assistance, then fell into a chair and life seemed to leave me for an instant. A glass of wine restored me temporarily and I reached the bed without assistance and lay down. Upon moving my feet on the bed I experienced a slight sensation of the bodily physical shock before produced on going down stairs in the morning. The physician arrived about 2 p. m. when the violent symptoms, especially vertigo, had somewhat subsided, but immediately after his leaving I was seized with a violent spell of vomiting, after which I arose from bed and went down stairs to be conveniently near some member of the family. About an hour later I was seized with a second attack of

vomiting, this time accompanied by the most awful dizziness imaginable. The doctor likens this condition to seasickness, but I am sure that no seasickness could be half so terrible. The nausea, vertigo and vomiting continued during the afternoon and were intensified by the slightest movement of any part of my body, the room seeming to spin round and round with great velocity. I was utterly unable to rise to return to my room and was finally carried there in great distress from the disturbance and change of position. Doctor called again at 7 o'clock in the evening and ordered absolute quiet, and I retired and slept heavily until morning. Upon awakening, all the symptoms returned with increased force, the slightest movement of any portion of my body, excepting my hands, producing the most deathly nausea and vertigo, together with a feeling as if I were falling to the affected side (the left), while the room would seem to revolve rapidly in the same direction, and the floor or objects under or below me seemed to rise up violently against me. These symptoms as before were increased by any movement of my extremities, even the simple movement of the eyeballs being sufficient to produce it, and it was only by maintaining an immovable position on my left side with my eyes closed that I enjoyed the least immunity from these distressing feelings. They continued without abatement for a week or eight days, when gradual amelioration took place, though several days elapsed before I was enabled to actually change my position on the bed; this was done by keeping the upper part of my body thoroughly rigid and horizontal, the least raising of the head or trunk instantly producing the feeling of shock and dizziness, yet without such violent recurrence of nausea. The inhalation of strong ammonia salts during these efforts at change of posture seemed to partially restrain the distress, especially the nausea. After the first week the vomiting ceased and in the next few days some abatement in the violence of the other symptoms, except movement, when the feeling of shock recurred as if the bed rose violently against me. This lasted during the entire three weeks I was in bed. In disappearing it seemed to leave the various parts of my body by degrees, beginning at the extremities and approaching my head, the last place to subside being the affected side between the shoulder and hip, where I still periodically notice it. On moving across it the bed seemed to rise like the ocean billows carrying me on their crest. As the vertigo grew milder the violence of this motion and the excursion of distant objects, seen through my windows, first grew less and less; nearer objects, as the confines of my room and its furniture, later, and finally my bed on which I rested. When convalescence had proceeded far enough and I could get up, I staggered considerably and pitched forward to the right or unaffected side. I was obliged to help myself by the bed and furniture, fearing to trust myself to others.

At the present time, six months since I was stricken, the noises continue with varying intensity, ranging from those heard on a quiet summer night, to those heard in a foundry. It is much less when lying on the affected side; and when lying on the other side, no matter what they may have been during the day or when up and about, they resemble the chiming of bells, and sometimes like the shifting of sand or rubbing of sand paper. External noises when near me sound abnormally loud, as for instance persons coughing or the tearing of paper, which are almost painful

and startling. I am unable to distinguish the ticking of a watch when held close to the affected ear."

I do not know that I can add materially to this excellent description by my patient of the subjective symptoms of the case and will therefore address myself briefly to those that are more especially objective.

On first seeing my patient, some hours after the inception of the attack, the symptom most complained of was the tinnitus, and my next visit, some five hours later, the triumverate, tinnitus, vertigo and nausea or vomiting; fullness and loud thumping noises were felt throughout the head, while sharper, higher pitched sounds and the vertigo were referred to the left ear. The patient, a robust, plethoric woman, seemed now to have some slight increase of color in her face, rather than the pallor usually attendant on the invasion of this disease. Pulse and temperature were about normal throughout her illness. The temperature never arose above 100 degrees F. and the pulse ranged between 75 and 90. Early and repeated examination disclosed no change in the drum membrane. At my first visit hearing power in the left was almost lost. So excessive was the vertigo and so easily excited or intensified that no little difficulty was experienced in making thorough examination. A heavy step or a slight jar of the bed, or the suggestion of a change in position for the administration of medicine or examination, were met with the most vigorous protests from the patient, who in other sicknesses had proven herself most tractable. At my first visits after some efforts for the relief of the nausea and vomiting, with but little effect, calomel in divided doses was given until free purgation, combined with acetanilid and citrate of caffeine, together with 1 gram doses of sodium bromid every three hours. The horrible tinnitus prevented her from sleeping, but this was fairly well overcome, by 0.65 gram of trional at bed time. On the evening of the second day, 0.016 gram doses of muriate of pilocarpin were administered hypodermatically every half hour until four doses were given, producing free though not excessive diaphoresis for a few hours, but making no impression on the disease. The next day 0.32 gram doses of potassium iodid, three times daily were prescribed, which in a few days were increased to 0.65 gram, and with the sodium bromid was the predominant treatment for several weeks. During the second week there were some manifestations of rheumatism in the extremities, which promptly disappeared on the administration of salicylate of colchicum. Absolute rest and perfect quiet were insisted on, and in the third week recovery was taking place, nausea disappearing first, vertigo and tinnitus subsiding later in the order named; both these latter, however, are still periodically present, a quick turn of the head, a violent motion of the body or a loud noise being sufficient to reproduce them.

Early in the attack Politzer inflation and the use of the Eustachian catheter mitigated the tinnitus but later, as Randall has pointed out in cases of internal ear disease secondary to disease of the conducting apparatus, intensified it. At the present time, six months after the attack, hearing power is improved, though for both high and low pitched tones it is still very greatly impaired, while loud tones of any pitch, especially if close, are painful. During the past month the bromid had been discontinued, and the iodid supplanted by Donovan's solution in ten drop doses thrice daily.

From observation in this and a number of other less typical cases, I conclude that it is a disease of more frequent occurrence than supposed by the profession at large, many of the milder forms and oft recurring cases being ascribed to cerebral troubles or gastric or visceral disturbances; the liver, long the scapegoat for human ills, is compelled to add this to its burden of offenses; especially is this so if occurring coincident with some indiscretion or irregularity of diet. The aurist is usually quick to recognize this disease even in its milder or atypical forms, but from the frequency with which I have found the ear ignored in attacks of vertigo, no reference by examination or otherwise being made to it, I think it is too often unrecognized until repeated attacks have worked irreparable injury. In the milder forms, rest in bed, restricted diet, attention to the excretory functions and the administration of bromid salts usually suffice. In gouty and rheumatic cases I have found salicylates or lithium salts, with potash and colchicum, most effectual. In the more severe cases, especially if at the outset they seem apoplecticiform in character with full tense pulse, I would not hesitate to bleed freely and follow by arterial sedatives and absorbents. Quinin, as advised by Charcot, I have found useful chiefly in cases with sluggish secretions and malarial complications, when the addition of arsenic or dioscorea villosa increases its beneficial effect. All that has been said concerning the milder cases, or concurrent complications, will apply to prevention of recurrence of the attacks, for I think it is fairly well established that one paroxysm predisposes to others subsequently.

SOCIETY PROCEEDINGS.

The Quarantine Convention of the South Atlantic and Gulf States.

(Concluded from page 433.)

FEBRUARY 10—MORNING SESSION.

The first paper read was

QUARANTINE AS IT AFFECTS PERSONAL RIGHTS,

by ex-Lieut. Gov. SHANDS of Mississippi, now professor at the law department of the State University. He discussed the question as to the extent laws can go in their effect upon the constitutional rights of the citizen, quoted from the Constitution as to the abridgement of the rights of the citizen, and said that any enactment interfering with the rights would be set aside by the courts. He also referred to a number of legal decisions touching upon the subject of his paper, and cited a Michigan case, emphasizing the position he took that laws bearing on the rights of citizens would not hold. He cited opinions, however, that quarantine laws were constitutional when the necessity of the enforcement of the provision abridging personal rights was apparent and necessary to public health.

Hon. C. H. AUSTILL of Spring Hill, told his experience with the yellow fever refugees last year, and how few personal rights individuals had during the quarantine. Mr. Austill thought, however, that if legal and reasonable quarantine laws were enacted it was the duty of the people to obey them. He deprecated very much the character of the quarantine laws established and operated last year.

A. L. McLEOD of Selma, said that the fever was a great evil and the quarantine also an evil, a lesser evil than the fever, perhaps a necessary evil; but a quarantine regulation should be a reasonable one. As it was last fall, in many instances it was a species of absolutism and despotism. He in the quarantine campaign last fall cited instances where the regulations had been extremely autocratic and despotic. He thought that the convention should recommend the passage of laws that would deprive a State, city or town of the right to quarantine other than infected places.

Hon. F. G. BROMBERG of Alabama, thought the remedy for

the mischievous features of quarantine was the proper education of the people. He said that in the end the courts would have to pass upon these rules and regulations. He thought that there should be a bureau of health at Washington the same as a Department of Agriculture. True ideas should be promulgated all through the country, and the people would be better posted and know better how to act.

The next subject of discussion was

NATION, STATE AND LOCAL QUARANTINE; HOW BEST TO ADJUST THEIR RELATIONS.

A paper was read on this subject by Dr. W. H. SANDERS, State health officer of Alabama. He took the position that local and municipal quarantine laws must be made subordinate to those of the sovereign State. The State must be the judge of the reasonableness of the quarantine laws of local and municipal government, wherever they conflict with those of the State. In her own borders the State should be supreme. Then assign to the National Government the duties of its own sphere. Let there be established a national bureau of public health. Let the members of it be from the different States, so the body could be in touch with all the different States. Let this body create rules and regulations in times of pestilence, and all the States would feel it incumbent upon them to support its laws, as all the States would have a voice in these rules. Dr. Sanders then presented a map of Alabama to illustrate the system he advocated. His plan was to have a health officer in every county, thoroughly familiar with the topography of his county, theoretically if not practically familiar with all infectious diseases, familiar with all the roads and avenues of traffic, and ready to act a moment's notice. The same to be with reference to the State Board of Health officer, except that he only familiarize himself with all the towns and cities near the adjoining States. In other words, to have a zone around the State guarded by the State health officer, assisted by his co-workers, so that the people within this zone could pursue their vocations undisturbed by the inconvenience of local and municipal quarantine regulations. Dr. Sanders, with the aid of the map, elaborated his plans in detail. He outlined his plans especially in opposition to a National quarantine system with one man from Washington in times of pestilence directing from that distance all the quarantine operations of the South. The necessary appointment of hundreds of thousands of quarantine officers at a short notice, officers, too, over whom the people of the South would have no voice in selecting. He predicted that such a course would result in trouble and a chaotic condition of affairs.

Hon. F. C. ZACHARIE of New Orleans divided the quarantine ideas into four classes. First, the people who believe in the absolute States rights, the second in the Federal sovereignty with reference to quarantine, a third class who believe in local and municipal quarantine, and a fourth class, composed generally of merchants, who would put the quarantine regulations upon a business basis, and would waive constitutional rights and home rule and depend upon the highest authorities to enforce quarantine regulations. Mr. Zacharie reviewed at length the great trade of the Mississippi Valley, how it was acquired and what it meant to the South. He intimated that Federal control of quarantine would be putting the South at the mercy of its mercantile enemies, and how easy it would be for the government to send down an expert to diagnose a case of fever as yellow fever and then close up several ports of the South for six months to the vast commercial injury of its cities and people and to the delight of the commercial enemies of the South. He referred to the malicious reports that had been circulated in the last two or three years against the South. The report, for instance, that grain which came to New Orleans and Mobile was damaged or ruined by reason of the dampness, and which report was found to be absolutely untrue. He believed that the Federal control of the quarantine would be disastrous to the southern business. He believed, however, that the Federal Government should define a reasonable quarantine and see that all vessels coming from infected ports were thoroughly disinfected and fumigated. Mr. Zacharie advocated forming a central society composed of delegates from all counties of the State to meet together and discuss hygienic and sanitary matters and give health information throughout the State, thus educating the people along that line.

Mr. FARRAR then offered the following resolution:

Resolved, That it is the sense of this convention

1. That it is the imperative duty of the Congress of the United States, under the power to regulate commerce with foreign nations and among the States to establish immediately a general system of maritime quarantine, and in pursuance thereof to locate on the Gulf and Atlantic coasts, at safe and convenient points, as many quarantine stations as the ex-

gencies of commerce may require, to which stations all vessels coming from infected or suspicious ports and bound to any port in the United States should, before presenting themselves for entry at such ports, be required to repair to and perform quarantine, according to uniform regulations, putting all the ports of the United States on an equality, reserving to such port, however, such reasonable right of detention, inspection and fumigation as the local *bona fide* health laws of such ports, not amounting to regulations of commerce, shall require.

2. That it is the imperative duty of the Gulf and South Atlantic States—Texas, Louisiana, Mississippi, Alabama, Georgia, Florida, Tennessee and South Carolina—under paragraph 3, of section 10, of article 1 of the Constitution of the United States, to obtain the consent of the Congress, and of the Congress to give such consent, to an agreement or compact between themselves for the establishment of a uniform system throughout these States of local quarantines and health laws, based on scientific principles and as little restrictive of traffic, transportation and intercourse as the health and welfare of the people will permit.

3. That in order to enable the Congress to have complete control over the localities selected for its quarantine stations, the States ought to, under paragraph 17 of section 8 of article 1 of the Constitution, to cede their jurisdiction to the Congress over all such localities.

4. That the line of demarcation between these State and Federal quarantine laws ought to be clearly drawn, so as to prevent all conflicts and jealousies between the officials charged with the execution of the same.

5. That all of these laws ought to be executed in a mutual spirit of conciliation and respect, so that by their combination and co-operation the safety of the people, which is the highest law, may be secured.

They were referred to the committee on resolutions.

Dr. J. B. ELLIOTT discussed the paper read by Dr. Sanders, and agreed with him in many things, but did not think Dr. Sanders valued sufficiently the most important thing in the convention, which was, in his opinion, "Who shall make the laws?" At present the quarantine laws are contradictory and unsatisfactory. He thought the convention ought not to adjourn until it had passed an explicit resolution with reference to those who should make the laws. A solid, durable system of quarantine laws, he thought, should be framed by a representative body, composed of delegates from each State, to whom should be delegated the power of making those laws. Under the present quarantine system the laws are arbitrary and despotic, and are naturally resisted by the people. Congress is not the proper body to make these laws. A presidential appointee can not make satisfactory laws. Dr. Elliott thought a legislative body ought to be appointed, composed of representatives of the different boards of health of the different States, to meet as often as necessary until a perfected system of sanitary and quarantine laws could be secured. He thought Congress should be appealed to on this question at once.

Dr. E. H. SHALL of Birmingham thought the great question was how best to keep yellow fever out of the country. This, he claimed, was the first principle, the first matter to be considered. He thought that regulations, tyrannic if necessary, should be adopted by Congress to prevent the fever from coming into this country. He thought that the Federal, State and municipal governments should work in co-operation to this end.

Dr. CUNNINGHAM of Alabama spoke of the importance of the convention and of the efficiency of the medical profession had they the means and power to handle yellow fever when in their midst. He maintained among other things that if Cuba were bought or taken by force it would greatly minimize the danger of infection from that island. He deplored the fact that Southern boards of health, the peers of any in the United States, had no money to fight yellow fever, and he believed that these delegates should demand the necessary money from Congress to carry on that work. He paid a high compliment to the Marine-Hospital Service, and thought the whole matter should be turned over to them, with the necessary money from Uncle Sam's treasury to do the work.

Dr. CARTER, in response to references that had been made to the Marine-Hospital Service, gave a short account of its workings.

Mr. RUSSELL thought that Federal and State quarantine systems could be drafted so that they could be in operation in the same State, even in the same town, just as they do now with the Federal and State courts and laws, without conflicting.

HARRY PILLS of Mobile said he had been impressed with the warning given by Colonel Zacharie of the Federal supervision of maritime quarantine. He thought, too, that it

might operate to the commercial disadvantage of the South. He said that Dr. Carter had answered in response to a question that even now there was a difference in the detention of vessels at ports north and south of Baltimore in favor of the North.

Mr. CLARKE of Mobile spoke of the matter of a board appointed by Congress to make quarantine laws. He said that Congress had not a particle of power to delegate to any other body the right to make laws. They might give that board a wide range, but could not delegate to it the power to make laws. As to Congress making an unjust discrimination against the South in the matter of the Federal supervision of maritime quarantine, Mr. Clarke did not believe it. He said if Congress had desired to discriminate against the ports of the South it would have done so by simply withholding appropriations, when in fact in the last ten years it had spent millions and millions of dollars on the ports of Galveston, New Orleans, Mobile and other Southern ports. He did not believe there was much diversity of opinion in the convention as to a national quarantine service to protect the Southern coast.

Professor SHANDS said in reply to Mr. Clarke that he thought that Congress could empower Dr. Elliott's proposed board of health office to make quarantine regulations as well as it now empowers the Secretary of the Treasury to make the regulations.

Col. ZACHARIE said Mr. Clarke's reference to appropriations for the South had been most unfortunate, and went on to tell how the East had always been given the preference in the matter of appropriations; how five times as much money had been spent giving New York three waterways as had been spent on the whole Mississippi River, draining twenty-one States. As to the present appropriation contemplated for the Passes, it was seen that the very men in Congress who sneered at the proposed appropriation were the ones who were from the East, interested in the appropriations for the East. He was sorry to say it as an American citizen, but the money powers of the East controlled the Government in the matter of appropriations for the East. He also alluded to the Union Pacific sale by the Government, and how the public press had, in that instance, prevented fraud by the Government.

Mr. CLARKE, in reply, said that if Col. Zacharie would examine the record he would see that there had been more money spent by the Government on the Mississippi River in the last ten years than on the New York harbor and waterways leading into it in the whole history of the Government.

Mr. MCLEOD of Selma offered a resolution to the effect that every State should pass laws with reference to quarantine and call upon the authorities of the different counties and towns to enforce them. The object of this was to prevent the shotgun quarantine.

Dr. MOODY of Mobile classed Dr. Sanders' system as a keynote of the situation.

Dr. KOHNKE replied to what Mr. Pillans had said about discrimination practiced against the South. He said there was a difference in the time of detention of vessels, but it was agreed to at a conference of medical men at which the South was represented. Had it been the same time for detention as in the South it would have been really a discrimination against the North, as yellow fever is much more easily introduced in the Southern than in the Northern ports.

Dr. ROBBINS of Vicksburg made a short talk in favor of national quarantine, and said he hoped the convention would not be turned from that by the appeals to prejudice and fears by the legal gentlemen.

AFTERNOON SESSION.

The Committee on Resolutions made a partial report against the bill in Congress now pending against vivisection. The committee reported as against the bill, that is, in favor of vivisection. It was discussed by Mr. Bromberg and Mr. Clarke of Mobile, Dr. Hamilton of Chicago and others. Mr. Bromberg opposed the passage of the resolution on the ground that it would be an officious interference with Congress; that if the bill in Congress was not passed, every "Tom, Dick and Harry" in the country with an "M.D." to his name would be engaged in vivisection. Dr. Hamilton of Chicago explained that the resolution was in the interest of science and ought to pass.

Mr. CLARKE thought the convention had its hands full in trying to advise the Senate committee on the quarantine question without going out of its way to offer advice on the vivisection bill. He thought the convention should devote itself to quarantine.

Dr. HORLBECK thought the matter perfectly germane to the quarantine question, as it was on the matter of the investigation of the yellow fever bacillus.

A long, uninteresting and general discussion followed, the resolution being finally adopted.

The national quarantine discussion was then renewed. Dr.

ROBBINS and Mr. FALKNER again made speeches in its interest.

Hon. LESLIE SHEEDON of Mobile said that the United States has the right to regulate maritime quarantine and the communication between States, and he thought there was a field for the operation of both the United States and the State Governments in which to work. He advocated Dr. Sanders' plan to be recommended favorably to Congress.

The report of the Committee on Suffrage was then taken up. It gave to the South Atlantic States and Southern States five votes each, and to the other States two votes each, voting to be on the unit rule. There was a long debate on the question as to whether the unit rule should prevail or not. When the vote came the unit rule was rejected by a vote of 56 to 34.

EVENING SESSION.

The first paper read was

A NATIONAL BUREAU OF PUBLIC HEALTH,

by Dr. U. O. B. WINGATE of Milwaukee. The Doctor presented a concise and clear argument for a national bureau of public health, which he advocated strongly as a means to help the South in controlling the yellow fever. He said the Marine Hospital Service had its hands full with its own work, and could not give the proper time nor consideration to this matter. Dr. Wingate thought that in addition to a national system of sanitation and quarantine there should be the same systems in the South in towns and cities to work in harmony and co-operation with the national organization.

Dr. DRAKE also in a paper on "National Quarantine," deprecated some of the statements that had been made by able constitutional lawyers against the Federal control of quarantine as well as some of the statements against the Federal Government itself. He began by a wholesale roast of the quarantine regulations last year, drew a picture of the general conditions, told of the failure of the local authorities in many instances to keep out the fever. He told of the stoppage of mails, burning of bridges and other lawless acts, and then in a very strong argument, advocated national quarantine hereafter to have control.

Dr. HORLBECK's paper was mainly a denunciation of the Caffery quarantine bill, as pernicious and likely to do a great deal of damage if passed. He intimated that it was made in the interest of commerce instead of public health. He said also that it gave undue rights and privileges to the National Government. He closed with the statement that national quarantine should be co-operative, not autocratic.

Dr. ELLIOTT presented an outline of a quarantine plan to be submitted to Congress. It was on the line of the quarantine council which he had advocated during the day. He presented it as a resolution and it was sent to the committee on resolutions without discussion.

Mr. FARRAR (by request) offered the following resolution, which was loudly cheered and sent to the committee on resolutions:

"Resolved, That the quarantine convention of the South Atlantic and Gulf States invite the attention of the Congress of the United States to Senate bill No. 2680, introduced by Hon. Mr. Caffery of Louisiana, as not conducive to the sanitary interests of the country. They do not regard the bill mentioned as necessary or wise. The powers proposed to be conferred to the Secretary of the Treasury are extreme and dangerous. We, therefore, respectfully recommend that said bill do not pass."

New Jersey State Sanitary Association.

(Continued from page 436.)

GEORGE F. LORING, Architect, of Boston, Mass., read a paper on

SCHOOL ARCHITECTURE.

He said: At the request of your president I propose to give you the result of my experience in school architecture. The relation between architecture and hygiene is close and vital. Building, the parent of architecture, owes its creation to the desire of men for more hygienic shelter than was furnished by forests or caves. After the erection of his own hut his belief in the humanity of the gods led him to provide the same comfort for them while his reverence caused him to change from mud to wood and to clay and to stone. By the erection of temples the esthetic element was introduced and developed. Architecture is thought of only as proportions and detail.

Why human energy should take this direction instead of developing the physical part of man may be found in the superstitious regard for the body itself. All the functions were thought to be controlled by superhuman forces; the mind being controlled by physical and religious abstraction tending to turn

the same away from the body, could but produce its own embodiment in architecture. The greatest achievements of architecture have always been identified with the most mental and spiritual activity. The greatest triumphs have been in its application to the arts and industries. If our architecture is true it will be influenced by our activities and partake of the influence of the time.

Our modern steel buildings with the improved mechanical and scientific apparatus, to a great extent typify the national characteristics and the life of the times. A true architect is born, not made, and he will not cast aside these facts or it will be looked upon as absurd.

Hygiene has been the last of all branches to develop, due to superstition and lack of knowledge. The microscope and the study of specialists has brought to our minds facts that have been concealed and laid for us a foundation on which to build: the application of these principles as applied to building of schoolhouses is the subject here treated. In this northern climate and congested population the average individual spends at least 90 per cent. of his entire life in doors. The sanitary conditions of our buildings therefore must exercise a powerful influence on the general health. The best means for a study of these problems is afforded by the public schools.

The large number of people of practically the same age, for the same length of time, under the same conditions placed in a given area, make it possible to deduce much more reliable data than can be done in any other way. Then also, children as a rule are free from chronic diseases or other diseases found in adults. Some one has said that a child may be regarded as a very sensitive hygienic instrument responding quickly to change and environment. Following this line of thought I have made a study of school construction from the standpoint of hygiene as well as architecture.

Sixteen years ago school buildings were erected with the idea that all that was required was the housing of so many pupils, protection from the weather and so much floor space, all at the least possible cost. At about the time mentioned I began an investigation of this subject, being assisted by a bright man who was principal of a school. Much has been written on this topic but my remarks are based on actual experience in this line.

Given a committee of fairly intelligent men, the first business instead of the last, which is the usual method, should be the selection of the architect. This should be done before any site for the proposed structure is purchased. The location at a suitable point within the school district, for convenience and accessibility, is acknowledged. The exposure of the school building is of the utmost importance and preferably the lot should face either to the north or the south: the class rooms can then be located on the southerly side of the structure without too long corridors.

We are advocates of the sun buildings for class rooms; we do not agree with those that advocate northwest or northerly exposure, when we consider the number of days in the year when the sun is obscured, that the sun is nearly vertical over us at its highest point in the summer time, that for spring, fall and winter days the sun is necessary for health; that east and west exposures in the morning and afternoon are as bad, in the opinion of those with whom we differ, as the southerly, and that the amount of fuel necessary for warming fresh air for northerly rooms is more by at least four tons per room than for southerly ones. We all know the agreeable sensation of direct sunlight. Sunlight is the only disinfectant which sustains man while it kills the microbe, and you can not but agree from the standpoint of health and economy that our conclusion is correct. We believe that the body is of as much importance as the eye, with the windows properly screened against intense sunlight by use of curtains to each window in two parts, with the rolls at the meeting rail, the top running up and the bottom one down, the light can be controlled.

All windows in class rooms should be square-headed without transom tops, which can not be properly curtained, and without the bar over the transoms, as they throw strong shadows over the desks. The light from the upper part of the window is most valuable and should not be made circular or in the gothic style. Double windows or four runs of sash should be built in on the cold sides of class rooms. They have the advantage of preventing the frosting of the glass surfaces and chilled air will not flow downward on the bodies of pupils that happen to be seated in the outer aisles. With double windows the wind pressure on the walls of the exterior does not affect the movement of the air in the heating and ventilating ducts. The interior lighting of corridors and location of stairways can be disposed to best advantage with the style of the building mentioned. The space surrounding a building and within the boundary of the property lines should be at least twenty feet.

A lot where the grade of the land falls, or so graded as to fall to the rear is much the better for the basement, and for access to the same.

Except for high schools, no building should have more than two stories of class rooms. By spreading the building over the ground, instead of vertically, we gain in breadth architectural effect, lessen the danger to health of young persons by loss of energy climbing stairways, and lessen the danger from panics; the additional cost of a building two stories high as to one of the same capacity three stories high is so small that it is not worth considering.

In fixing the heights of stories we are governed some by the amount to be expended; the proper height of basement should be nine feet six inches to ten feet, of first story thirteen feet and second story twelve feet. The light in rooms on the second story is always superior to that on the first and we therefore increase the height of the story and of the glass surface of the first story to equalize the same: in any event the window heads should be finished to the top so no shadows can be thrown on the ceilings. The sill of windows should be three feet four inches from the floor. The proportion of light to floor of class rooms should never be less than one square foot of glass surface to six square feet of floor surface, and from experience we can say that this holds good for rooms thirty-eight feet wide, lighted from one side only. Within the limits of a city where adjoining buildings are about twenty feet from exterior walls we should increase our glass in proportion of 1 to 5.

Every room should receive the direct rays of the sun for some part of the day. The special arrangement of curtains before mentioned we consider better than dusty and rattling shutters. The direct rays can be wholly or in part excluded if desired, in direct sunlight the rooms up to the limit mentioned are sufficiently bright to allow the reading of extremely fine print without exertion; at other times the shades are not required.

The worst light is from the front. The best light is from the left side or left side and back. As the teacher suffers from the light as well as the pupil, and is placed necessarily in the opposite position, we believe that the desk should be placed on the floor, in such position as may suit the individual taste; supplemented by swivel chair is convenient and comfortable. The ceiling plays an important part in the distribution of light and should be white. We have used stamped metal ceilings painted white, but they are objectionable on account of the many shadows they throw; the paint soon becomes dull and is not the equal of a perfect plaster ceiling for reflecting light; the walls are better for the eye if tinted. Nothing can be better for blackboards than natural slate, but the joints should be cemented together after being placed; the chalk receivers should be placed at a height of two feet two inches from the floor for small children, and not over three feet four inches for high school pupils. Blackboards should not be placed between windows, and from thirty feet to forty feet in length is sufficient for any class room. Dustless crayons should be used; if common ones are used the board should be wiped off with a damp cloth, and not with a dry brush. Slots in the top molding of the boards should be left for cards. Picture moldings should be placed everywhere.

The number of pupils to a room can only be decided by the committee in charge.

The sizes of rooms for good seating depends on the size of the desks and ages of the pupils. The blackboard aisle should be three feet eight inches, the exterior aisles two feet four inches wide, inside aisles never less than twenty one inches. An average desk twenty four inches wide, fifteen and a half inches deep, with chairs thirty one inches from back to back, seating grammar school pupils up to the age of 14, allowing space for teacher, will make a room twenty-six feet six inches by thirty-four feet three inches and allow fifty-four seats when fronted the narrow way, or fifty-two seats when fronted the wide way of the room. We find by careful adjustment of sizes of seats and ages of pupils that it is not necessary to allow twenty square feet of floor surfaces per pupil. As most authorities state they do not make any allowance for the age and place small and large on the same footing, we estimate fifteen square feet for the primary, seventeen square feet for grammar and twenty square feet for high schools. This makes quite a difference in the area and cost of a building. The adjustable desk with adjustable seat having a back of one curve seems to us the best and most comfortable for pupils. In a room longer than thirty-six feet it is difficult for a teacher to speak in an ordinary tone of voice so as to be clearly heard by the pupils in the rear row of seats.

Corridors should be without obstruction and never less than eight feet; ten is better. Stairways should be six feet wide

and each flight broken with a landing. These stairs should be as near the exits as possible and also equally placed at each end of the building. No portion of entrances, halls, corridors or stairs should be so planned that one teacher in charge of a floor can not command a view of the same for maintaining discipline.

Stairs, if of wood, should have stringers or supports of heavy hard pine, or of iron. If of iron, flat pieces of sheet lead should be sunk in each tread or sinkage filled with asphalt. The rise should never be more than seven and a half inches for each step with eleven inch treads.

From each class room there should be two doors connecting with the corridor; these doors should be hung to swing both ways; they should be fitted with new spring check, so whichever way they swing they stop on the return, at the center; glass panels in these doors are necessary.

If proper stairways are put in, there is no necessity for fire escapes on the exterior, any more than it is necessary to put up unsightly ventilators on the roof if proper system of ventilation is installed. If the building is laid out as described there can be no dark places. The details of lunch rooms, laboratories, specimen rooms, principal's office, teachers' rooms, libraries, superintendent's office, supply rooms, are matters for consultation. The female teachers' room should have toilet conveniences so that the girl pupils could use it for a sick-room; lockers for the teachers should also be placed in that room.

Laboratory walls should be of brick if the building is of brick, and finished in enameled brick or enameled paint; floors of the same should be of granolithic or asphalt. Floors of basement should be of granolithic; concrete is cheaper and also poorer in wearing qualities, as it disintegrates; much of the dirt on the floors of corridors and class rooms is from this source. The boiler room floor should be paved with brick and grouted in cement; the ceilings of basement where wooden framing is used in floor above should be wire lathed and plastered and is a protection against noise, dirt, drafts and fires. The best flooring for upper floors is selected dry maple or conagrained hard pine, and the boards should be narrow, matched, and blind nailed. If nailed in the ordinary manner every nail hole and crack is a place for deposit of human and animal wastes. The floors may be covered with two coats of elastic varnish that will not mar or scratch; they should not be oiled as that turns hard pine black.

If wooden construction is used for floorings then the same should be protected against fire by use of salamander fireproof sheets put down between the under and upper floors with lapped joints and coated over with a solution of that make. If the partitions are of wood, then they should be fire stopped at each floor and ceiling. If brick walls are furred off for plaster and finish, the same should be fire stopped at top and bottom in each story. All staircases should be carried by brick walls and they should not be laid out in plan so as to be over the boiler room.

Concrete-expanded metal lath and steel construction for fireproof floors would cost about seven cents per square foot more than wooden construction and we hope the time will soon come when committees will be willing to pay the additional cost.

In the disposition of the basement plan the space instead of being filled with pipes, ducts, boilers, piers, etc., can be so planned as to have good rooms available for wardrobes, if desired, for toilets, manual training rooms, janitor's room, bicycle rooms, lunch rooms, etc., whereas, in many schools this portion of the building is absolutely worthless and can not be utilized, show lack of knowledge and experience on the part of the designer.

Assembly halls are usually placed in the roof space for economic reasons. The first or second floor would be safer and more convenient; if located on the second floor by providing wide openings to each adjoining class room at the platform end of the hall. The accommodations can be increased by using these class rooms, and allow of a smaller hall if necessary. From motives of economy the hall may be used as class rooms and arranged with folding partitions; the platform may be in sections, removable and a storage place provided. Quite often we arrange two class rooms so that they may be thrown together, making one large room; if on first floor they may be used for town purposes, etc. Regarding acoustic qualities of class rooms with height of from twelve to thirteen feet, the proportions of 26 x 34 or 26 x 32 are always good.

Authorities differ regarding the width of class rooms and quality of light; one says width of room equals two and one-half times top of windows from top of desks; this would give about twenty-six feet width for thirteen foot story and twenty-four feet width for twelve foot story. When there are no limitations the nearer this rule is adhered to the better the result.

The wainscot work of class rooms and elsewhere would be more vermin and dust proof if made of hard plaster painted four coats of lead and oil with soft gray color and finished with-out a gloss. Standpipes and fire hose should be furnished where the appropriation admits of it. The interior finish should always be of ash or oak, and the additional cost for ash over whitewood (which is so often used) would never be known if incorporated in the specifications. The style of the same should be simple and free from too many projections to catch the dust.

Wardrobes.—As contagion is most likely to occur from garments, which being porous, absorb and transport gases, microbes, etc., it is necessary to have two wardrobes properly arranged on each floor, one for each sex if appropriation permits. The latest improved wardrobes set up in separate rooms or in corridors either in the basement or on each story is made with separate stalls of three to four inch by three to eight inch channel irons covered with three to four inch half oval with open spaces up ten inches from the floor and the top five foot four inches from the floor, between each stall and forming the back between two sets of stalls on these frames filled with one and one-half inch diamond mesh No. 9 wire. At the bottom is a shelf for rubbers, two rings and cups for umbrellas with hangings on each side, none on the back. They are about one foot three inches deep and one foot six inches wide. The cost of this style of wardrobe put up is about \$1 per hanging, as there are two to each stall, \$2 per stall. In estimating the number of stalls that can be placed in a room and have plenty of freedom for aisles, etc., allow two square feet per hanging. We believe the best place for wardrobes is in each corridor, provided it is wide enough. There will be no traveling up and down to the basement. If separated for sexes there is less crossing of files or pupils, being more direct, cleaner and just as well ventilated.

Wardrobes seem to be the most difficult part of school sanitation, there being many advantages in the open method by placing them in wide corridors or in the basement, unless an appropriation large enough for special rooms with a thorough circulation of fresh air, is provided. The advantage of having them in the corridor is that the teacher in command of that floor maintains the discipline.

Sewerage.—Where there are no sewers we unhesitatingly use the cremating closets, but these should never be supplied with foul air drawn from class rooms above; there should not be a connection of any kind between closet room and rooms above. In no case should the wastes of sinks and bowls or private toilets be discharged into these vaults; the wastes should enter a cesspool, preferably a double cesspool a tight one for solids and a leaching one for liquids. The best urinal is of slate with the dry air system, using no water. There should be a connecting waste from the trough and a connection made to the cesspool drain. We are sure from the experience we have had, that these, when properly erected, will last forever without repair and that they are free from odor: if an earthen urinal is desired, the best is the Stevens' patent, ventilated from the bottom of the bowl and automatically flushed; slate is the best material for slabs.

Water-closets for pupils' use, where there is water carriage, should be with automatic seats. The Hellyer Oxford Closet, a moderate priced vitreous earthenware product of this country, has lately been fitted with a perfect seat, absolutely sure in action, and not likely to wear in any part; these closets set with a space of from twenty to twenty-four inches between the back of the slab and wall will allow access to all the pipes, points, and tanks; nothing but the closet is exposed to view; the closets are set separately with separate tanks, enclosed in ash, slate or marble partitions six feet six inches high; doors should stand open in the closet with spring attachment and with spaces at top and bottom; each closet should have seat ventilation, and the toilet-room should be supplied with fresh warm air and a foul air extracting flue. No metal ducts for fresh air supplies to class rooms should be allowed to cross the ceilings of these rooms, as the joints in the metal work and around brick openings can not be made tight, and the fresh air becomes foul. There is no particular advantage in placing the toilets in an annex with cut-off outside the building, except that it is more convenient to have these on a level with the class room floors, in which case the building will be more costly.

The thick porcelain slabs with backs are the neatest and best device for drinking fountains in the corridors; or, if economy is the word, you can obtain an iron fountain with push button instead of a faucet, and when painted white is neat, serviceable and cheap. Each pupil should have an individual cup or glass, and place for the same should be provided either in individual wardrobe, stall or desk.

The principal's and teachers' rooms should be fitted with water-closets and bowls of approved make.

There should be two sill cocks and supplies at the ends of the building with shut-offs inside and a hose bibb and sink for use of the janitor in the boiler-room. The practice of making one large foul air extracting flue answer for two or more rooms should never be allowed, it being a conductor for sound and foul air between all parts so connected. Each room should have an independent outlet.

Cost of school buildings.—As we understand it, structures for this purpose are not to be erected as monuments to committees or the architects, they should be business buildings, neatly and plainly treated for the purpose, but not necessarily built like factories; it does not cost much to get breadth of treatment and architectural effect in a modest way. Unfortunately we have always been limited to cost. We can honestly say that the appropriations have never been exceeded; to the best of our ability we have included as much of the above points as the money at our command would allow. For high schools of brick and stone the price per cubic foot of contents varies in different localities from 11.2 to 12.5 cents; per square foot of ground covered for two stories of class rooms from \$5.50 to \$6.50, for three stories of class rooms \$7.50. The cost per pupil averages \$160 to \$175.

The Montclair high school erected by us in the year 1892 cost as follows: per cubic foot 12.3 cents, \$6.42 per square foot of area of first floor, or \$160 per pupil, and accommodates 605 pupils. The most expensive schools we ever erected cost 15 cents per cubic foot, a limit which there is no necessity for exceeding. Brick grammar schools without assembly halls cost per square foot of first floor area from \$4.50 to \$5.50 and from 9.8 cents to 11.34 cents per cubic foot, and per pupil from \$68 to \$75. Brick grammar schools with assembly halls will cost about \$80 to \$85 per pupil. Wooden school buildings without assembly hall cost from 7 to 8.4 cents per cubic foot, \$3.25 to \$3.78 per square foot of first floor area and from \$50 to \$60 per pupil. Wooden school buildings with hall cost per pupil about \$68.

The above prices include the building complete, including heating, ventilation, sanitary appliances and architects' services, without furniture. In estimating the cost of furniture, using adjustable desks of birch, adjustable seats, teacher's desk, swivel chair, extra chair, clock and shades, the cost per class room for primary schools is \$167, for grammar schools \$200, for high schools \$250.

Dr. O. W. BRAYMER of Camden read a paper on

INFANT MORTALITY AND ITS CAUSES.

He said the frightfully great mortality is a well-known fact. The first year of life is the period of the greatest loss. Fifteen out of every 100 die; four times as many die in the first as in the second months; and almost as many during the two years after. One-tenth die before the eleventh day. Winckel says that 10 per cent. die before the eleventh day; one fifth to one-fourth before the end of the fifth year; 20 per cent. before they are six months of age. What is the cause? There are several. Physical defects at birth; feeble system; proneness to contagious diseases; unwholesome surroundings; improper food; defects due to defective ova; maternal impressions or injuries, and diseased parents. Much can be done to reduce this rate from contagious diseases. The last causes we can readily see how to relieve. Congenital defects should be prevented by proper dress of the mother, as tight corsets or clothing prevent the expansion of the uterus during pregnancy. Injuries cause many defects, as blows, etc. Syphilis or tuberculosis also produces feeble offspring. Again, when births are too frequent the children are not strong and are made feeble by improper nutrition, and want of care. A blot on the enlightenment of the age is to allow felons, the syphilitic, the tuberculous, the weak-minded, etc., to propagate without restriction. These bring into the world children of no utility. Man is below all beasts save monkeys in having no control of his sexual desires. In rearing blooded animals, we expect to have the birth at the proper time of the year, of pure stock, and in a first-class condition. It is not so with the human being: no thought is given to this; children in the best families are not looked upon with joy. The authorities do not take enough interest as to hygiene of the home, and all that will conduce to the production of healthy children. The common people are not taught as to the value of cleanliness, fresh air, proper clothing; all this should be impressed upon them by persistent education along sanitary lines. It is difficult to make people believe that children should be dressed not as to season, but according to the temperature. There should be an interdiction of the old nurse's bottle with the tube by every board of health. This is the source of much injury to nursing children, as causing bad food to be taken during the time of nursing. We should

go everywhere and teach morality, cleanliness and common sense; into the school room and teach sanitation in its fullest points; how to live and how to die; teach physiology of life, purity and health. We must not allow pride and the prevailing fashion and public opinion only to govern the growing child. Then the legislature must enact laws to prevent marriages of cripples, degenerates and the unhealthy. The conscientious minister must assist from the pulpit; he should be a physical exponent of the hygienic laws. The legal profession must assist by enforcing the laws so enacted; all can help by teaching hygiene and sanitary science, and the great reform can be quickly and easily obtained if the National government will heed the crying need and give us a Department of Public Health.

(To be continued.)

SELECTIONS.

Vaccinia Inusitata.—Dr. Lamb reports two cases of unprepared vaccination, as follows: "On Nov. 21, 1897, I was called to see a man and his wife, having six weeks previously vaccinated their child. The parents had during this period been attending to the child's arm, which was discharging some clear fluid, and the vaccination marks were covered with brownish crusts. No definite history of inoculation could be got: but on several occasions the husband had attended to the child's arm before getting out of bed, and had then urinated without previously washing his hands. On November 17 he complained of some pain and tenderness in the groin and also noticed some swelling in that region. He discovered some marks on his penis but did not take much notice of them. On the same day his wife had pain on micturition, but had no vaginal discharge. On the 18th the swelling was more noticeable and the pain and tenderness were much increased. His wife also had a small swelling in the right groin. On the 21st both husband and wife were worse. On examining the husband I found the horizontal inguinal glands were much enlarged on either side, and were also painful and tender. On drawing back the prepuce I saw five typical vaccination marks about a week old on the glans penis. The vesicles contained a very small quantity of lymph. There was no urethral discharge. His wife had two vaccination marks one just inside the labia and the other at the margin of the orifice of the urethra, the latter accounting for the pain on micturition. They seemed to be about the same age as those on the glans penis of the husband. There had been no sexual intercourse since the 14th. On the 22d the conditions were more aggravated in both cases. In the husband's case there was some swelling of the penis, and by the 23d that had become so great that the prepuce could not be retracted, and there was some discharge coming from the glans but none from the urethra. On the 27th the glands in both were nearly their normal size and all the local conditions in both husband and wife were not so great, although the wife had still some pain on micturition and a slight discharge from the vagina. On the 29th the husband returned to his work and his wife was able to resume her house duties without any discomfort. The mode of onset and the subsequent history with their complete recovery in so short a time leave no doubt as to the true nature of the case.—*London Lancet*, January 1.

Treatment of Chlorosis.—Dr. Latham of London writes to the *Practitioner*, October, an interesting contribution regarding the treatment of anemia and chlorosis. He has found the following treatment serviceable in many cases of chronic chlorosis:

Tinct. ferri perchlor	m. x xx.
Sp. ætheris sulph	m. x xv.
Tinct. nucis vom.	m. x.
Tinct. quassiae	m. xxx xl.
Aq. ad	℥iiss.

To be taken twice a day, an hour before luncheon and dinner.

It has been said that when iron is tolerated in chlorosis, the

remedy "is only effectual when given in large doses"—in such doses as will render the alkaline sulphids formed in the intestine inert. I dissent altogether from this plan of treatment. Large doses not infrequently set up considerable intestinal irritation, a febrile condition, palpitation or headache. "Every physician is acquainted with the symptoms which arise when young girls have taken large doses of iron for some time. Irritation of the abdominal organs, which evidently begins in the intestine, is set up, and may extend to the peritoneum and be accompanied with the usual symptoms, pain, discomfort, a tendency to vomit, diarrhea or constipation and general exhaustion; the last, however, not being apparently dependent upon the condition of the abdominal organs. These symptoms may persist for some days even when the iron is immediately discontinued, and may then gradually subside."

It is well then not to exceed moderate doses of iron; but, if necessary, we should endeavor to limit the formation of the alkaline sulphids in the intestine by other means. One of the most effective ways of doing so is to ensure a daily, satisfactory and natural action of the bowels. Constipated bowels may, as Sir Andrew Clark pointed out, lead to the absorption into the circulation of toxins, which then have a destructive action upon the red corpuscles.

An Irish Surgeon's Adventures in Turkey.—Surgeon Charles S. Ryan, formerly with the Turkish army in the warfare of ten years ago, has written a charming narrative of his experiences in the Orient. The *Lancel* dubs the book by the title "Phil Fogarty II." for the adventures which the author relates are even superior to the experiences of the Thackeray-Lever hero. Dr. Ryan is an Australian Irishman, and evidently possesses qualities eminently suitable for an army surgeon; indomitable pluck, cheerfulness under the most depressing conditions and, above all, the quality of sympathy. Dr. Ryan finished his medical education at Edinburgh University and was enjoying a holiday when he saw an advertisement from the Turkish Government inviting applications to serve as an army surgeon. He at once applied and was accepted, and the first post to which he was appointed was the camp outside Widdin. Of his work here he gives the following picture: "Half a mile from the camp was a large marsh or swamp, where great white arum lilies grew, with jonquils, narcissus, and the different kinds of iris in magnificent profusion, as well as millions of the tiny white snowflakes. I had a trench dug outside my tent, and once a week our two servants . . . brought back barrowfuls of flowers, which I planted in the trench. Here, too, the orderlies made us a great seat of turf and every morning from six o'clock till half past nine, I sat there among the flowers to receive my patients, who used to come up from the various battalions to have their ailments treated. As I sat on my throne of turf I had a sack full of Epsom salts beside me, together with a bucket of water and a pannikin, so that when the patient had swallowed a handful of salts I presented him with a pannikin of water and washed the nauseous mouthful down." Dr. Ryan was soon, however, to see very different work. His account of the siege of Plevna and the appalling state into which the hospital got toward the end of that magnificently borne time of trial reads like a chapter from the "Inferno." We must not quote any more, but will only say that after getting out of Plevna, Dr. Ryan volunteered for service with the Stafford House ambulance for service in Erzeroum. Here things were, if possible, worse than in Plevna. Typhus fever, cold and starvation added to the misery of wounds made up a terrible tale. We can sympathize with Dr. Ryan's trials on his journey from Erzeroum to Trebizond, and from a personal experience of the country we know what he must have undergone. Every one should read this book; it is a plain unvarnished tale of what goes on in war, and takes us back to the simplicity of MM. Erckmann-Chatrian, whose war stories are, we think, superior to those of Zola, except perhaps his "Attaque du Moulin." The style is easy and eminently readable.

Some Animal Substances used as Remedial Agents a Century or More Ago.—*Human skull* (cranium hominis). The powder, in doses of one dram, used in epilepsy; those a long time buried said to have been preferred, and some even limited the remedial action to the os triquetrum (bone of the carpus, situated between the os lunare and os orbiculare).

Paring of the nails (rasura unguis). A common emetic.

Mummy (mumia). Either that brought from Egypt, or prepared by dipping muscular flesh in spirit of wine and hanging it up in a brisk draft of air, or smoking it like ham. Used in bruises, epilepsy, asthma, phthisis, in powder $\frac{1}{2}$ to 1 dram. Classified by one writer (1753) as a vulnerary.

Puppies (catelli). Live puppies, split in half and applied while warm; employed as poultices "to draw venom" from sores or boils. The puppies were sometimes boiled first in oil to make the poultice "mucilaginous."

Wolf's liver (hepar lupi). Used dried in diseases of the liver.

Fox lungs (pulmones vulpis). Used when dried and powdered in a pectoral linctus. This remedy was a great favorite among the common people. One writer says that the lungs of a fox must be a specific for asthma because "that animal is remarkable for its strong powers of respiration."

Huckle bone of the hare (astragalus leporis, talus leporinus). Diuretic powder.

Hare's fur (pili leporis). Styptic.

Musk (moschus). Antispasmodic and diaphoretic. The author of the New Dispensatory (1753) quaintly remarks that in his day "it has been for some time out of use, even as a perfume, on a supposition of its occasioning vapors, etc., in weak females and persons of sedentary habits."

Elk's hoof (ungula alcis). Anti-epileptic, either worn externally, so as to touch the skin, or taken in powder in doses of one dram. Said to "smell very sweet, by which it may be distinguished from a buffalo's hoof, which is sometimes sold for it."

Bone of a Stag's heart (os e corde cervi). Cardiac, esteemed to remove barrenness and prevent abortion. Dose, in powder, one dram.

Hartshorn shavings (rasura cornus cervi). The horns of the buck or fallow deer. To quote the New Dispensatory (1753), "Many extraordinary virtues have been attributed to these horns, and to all the parts of the animal in general; but experience gives no countenance to them; nor do they seem to have any other foundation than the great timidity of the hart, the annual removal of his horns, and an opinion of an extraordinary longevity; from these circumstances it was inferred that all parts of him must be proper for intimidating the enraged archer, renewing health and strength, and prolonging life."

Boar's tooth (dens apri). Used as hartshorn shavings, but of greater value.

Rhinoceros horn (cornu rhinocerotis). Alexiterial, in powder; dose one dram.

Unicorn's horn (cornu unicornus). Resists the operation of poisons.

Inward skin of the fowl's gizzard (pellicula stomachi gallinae interiores). "To strengthen the stomach."

Egg shell (caro testudinis). "Highly nutritive, analeptic and antiscorbutic." (Gray.)

Skinks (scinci). Dried, salted and powdered skins were considered alexipharmic, aphrodisiac and diuretic. Were also used in the preparation of the "mithridate."

Scaly lizard (lacerta agilis). Was sometimes used instead of skinks.

Vipers (viperae). Both live and dried; were official in the Edinburgh Pharmacopoeia and considered "alexiterial, sudorific, depurative and very nutritive." An old work on materia medica discusses the subject in part as follows: "The viper or adder is one of the viviparous reptiles, without feet, about an inch in thickness, and twenty or thirty in length. The poison of this serpent is confined to its mouth, at the basis of the phangs, or long teeth which it wounds with, is lodged a little bag containing the poisonous liquid, a very minute portion of which, mixed immediately with the blood, proves fatal; our viper catchers are said to prevent the mischiefs otherwise following from the bites by rubbing olive oil warm on the part. The flesh of the viper is perfectly innocent and strongly recommended as a medicine of extraordinary service in scrophulous, leprous and other obstinate chronic disorders; its virtues, however, in these cases are probably too much exaggerated. The viper is undoubtedly an high nutritious food, and hence, in some kinds of weaknesses and emaciated habits is not undeservedly looked upon as a good restorative. To answer any valuable purposes, fresh, vigorous vipers (not such as have been long kept alive after they are caught) should be liberally used as food; the wines and tinctures of them can scarce be supposed to receive any considerable virtue from the animal; the dry flesh brought from abroad is entirely insignificant."

Toad (bufo). The toad "dried by a gentle heat and pulverized" was greatly esteemed as a diuretic and antihydrotic. Dose in powder, to one dram. Applied externally to the abdomen to restrain "haemorrhages." "Bufo Præparatus" or "prepared toad," was officially manufactured by the old Edinburgh Pharmacopœia as follows: "Put live toads into an earthen pot and dry them in an oven moderately heated till they become pulverable."

Prepared goat's blood (sanguis hirci præparatus, Edinburgh Pharmacopœia). "About the beginning of summer, take blood from any convenient artery of a middle-aged goat and expose it in a clear vessel to the sun, or a moderately heated oven, till sufficiently dried." Paris, the author of "Pharmacologia," and professor of materia medica in the Royal College of Physicians, London (1819-21), quoting from Browne's "Vulgar Errors," states that in many of the ancient works on physic, the blood of the goat was extolled for its efficacy in dissolving stones, and from this supposed lithotriptic virtue, it forms the principal ingredient of the "Powder of Nicolaus" and of the "Electuary of the Queen of Colein." The expression which gave origin to this belief was evidently allegorical, signifying that the blood of the goat, by which our Savior was typified, was capable of softening the stony hearts of his enemies, or according to others, that by his influence the stony rocks and veil of the temple were shattered.

Frog's spawn (eperniola, ranarum sperma). "Celebrated as an excellent cooler for external purposes"; also used as an ingredient of a distilled "simple water."

Salamander (salamandra). Prepared by infusion in oil. Used by internal administration as a diaphoretic; externally, useful in rheumatism.

Bone of the perch's head (os e capite perciae). Absorbent, lithotriptic; externally in tooth powders and to dry ulcers.

Pike's jaw bone (mandibula lucii). In powder, useful in leucorrhœa and to facilitate labor; dose 1 to 2 drams.

Liver of eels (hepar anguillæ). Used dried and powdered, to facilitate labor; dose 1 to 2 scruples.

Hog lice, wood lice (millipedes, etc.). Alive, No. 12 (Gray) or dried and powdered, in dose of one to three scruples; used as a diuretic, "aperitive," and in the treatment of jaundice. Millipedes were official in the early editions of both the London and Edinburgh Pharmacopœias.

The insect kingdom was also called upon to furnish scorpions, beetles, bedbugs, ants, bees and a number of other substances, like cantharides, cochineal, etc., used more or less at the present time.—*Pharmaceutical Era*, January 6.

PRAGTICAL NOTES.

Negative Antibacterial Effect of Tannin. Sabrazés states that tannin has no antibacterial effect. On the contrary, it rather seems to favor the development of Koch's bacillus *in vitro* and in the guinea pig.—*C. R. Soc. de Biol.*, 1897, No. 40.

Lymph Glands in Carcinoma.—The importance of exterminating the lymph glands even down to the base of the broad ligament, in carcinoma of the uterus, as in carcinoma of the mamma, was emphasized at the Moscow Congress, and for this reason the abdominal route recommended.

Absorption of Antitoxin In the Alimentary Canal.—Escherich has established the fact that diphtheria antitoxin is readily absorbed by infants if administered per os or per rectum, but that it is not absorbed by older children or by adults when administered in this way.

Chlorid of Zinc in Gynecology.—For cauterizing the uterus after curettement, or in case of erosions, Schlapobersky has found a 20 per cent. solution of zinc chlorid extremely effective and satisfactory in every respect. *St. Petersburg Med. Woch.* December 25.

Powders for Migraine.—Antipyrin and potassium bromid, aa. 50 centigrams; cocain hydrochlorate, 1 centigram; caffein, 2 centigrams; pulv. paullinia sorbilis, 30 centigrams. For one powder. Make six. Take one at the first indication of migraine.—A. Rohin in *Semaine Méd.*, January 19.

Xerophthalmia.—E. Neznamov cures xerophthalmia by bathing the conjunctiva with a salt solution to which a little sodium bicarbonate has been added; then swabs lightly with sul-

phuric ether on a cotton tampon. The lachrymal secretion is also stimulated by an occasional whiff of some ammoniac liquid during the day.—*Semaine Méd.*, December 29.

Bronchial Asthma.—The injection of a Pravaz syringe of the following fluids will sometimes arrest an attack of asthma; occasionally two or three injections are required: Morphin sulphate 75 milligrams; strychnin sulphate, 1 centigram; hyoscin hydrobromate, 3 milligrams; aq. dest. 10 grams. For hypodermic injections.—S. Solis-Cohen, *Semaine Méd.*, December 29.

Anesthesia of the Urethra by Rectal Injections.—Morphin hydrochlorate, 15 centigrams; atropin sulphate, 5 milligrams; aq. dest. 50 grams. For external use. Two to four grams of this solution injected into the rectum will completely abolish sensibility in the posterior urethra.—M. Scharf, *Progrès Méd.*, December 25.

The Value of Filmogen is cordially endorsed by Unna in the *Monatsh. f. prakt. Dermatologie*, Vol. xxv, No. 4. It is an insoluble varnish superior to collodion, etc., for several reasons, taking up medicaments readily and adhering to moist surfaces. Unna has obtained remarkably favorable results in infantile intertriginous eczema, with 5 per cent. ichthyol in filmogen (*vide JOURNAL*, Vol. xxvii, No. 24). It is readily removed with alcohol or ether.

Treatment of Orchitis.—Du Castel disapproves of keeping patients with orchitis in bed, and has been very successful with a compressing cotton-lined suspensory, allowing the patient to pursue his usual occupations, after the pain has been relieved by painting the effected part with methyl or ethyl chlorid, which produces refrigeration similarly to ice, recommended for the purpose by Diday. He has cured in this way cases complicated with severe vaginalitis, and in chronic cases rebellious to all treatment finds this method as satisfactory as any. *Semaine Méd.*, January 19.

Aluminium Acetate in Uterine Hemorrhages. The hemostatic, antiseptic and astringent properties of this substance render it an effective means of arresting hemorrhage from the uterus, post partum or otherwise. Kalenscher makes the injection through a rubber tube attached to the end of a syringe holding 20 to 30 c.c. of a 3 per cent. solution, introducing it into the uterus. The astringent power is such that the vagina contracts until it is difficult to insert the finger. Three to five injections are usually required.—*Semaine Méd.*, January 19.

Alcohol as a Disinfectant.—Recent researches seem to show that absolute alcohol is devoid of all disinfectant properties, whereas proof spirit (50 per cent.) gives more tangible results in this direction than either stronger or weaker solutions. Antiseptic substances which, in aqueous solution, are more or less active germicides, entirely lose this property when dissolved in strong alcohol, but, on the other hand, corrosive sublimate, carbolic acid, lysol, and thymol, dissolved in a 50 per cent. solution of alcohol, disinfect better than aqueous solutions of the same strength.—*Med. Press and Circular*, January 26.

Organ Therapeutics in infantile Nephritis.—Concetti announces extremely favorable results from the administration of renadene (an article manufactured from the kidneys of young pigs, mixed with sugar of milk) to six children under 5 years of age. Three were cases of acute primary nephritis, the others were chronic cases consecutive to scarlet fever or whooping cough. As much as four grams a day were given and it was always well tolerated. The improvement in the general condition was "rapid and conspicuous," and all the local symptoms progressively disappeared. The acute cases were attenuated and promptly recovered. The usual hygienic measures were applied at the same time.—*Gaz. d. Osp. e d. Clin.* December 26.

Iodoformed Salol in Tuberculosis of the Bones.—P. Reynier confirms his former announcement in regard to the benefit derived from salol heated to 48 degrees C. with iodoform (at which

point it melts, crystallizing into a solid mass as it cools), injected into tuberculous lesions of the bones, the soft parts over it sewed up at once, without drainage. In one of the six cases he reports, the patient's leg was amputated one year after on account of the spread of the disease. The injected spot was found entirely healed, the salol forming a solid adherent block, hard to be detached. The Soc. de Chir. does not endorse the method, observing that it promises no better than Reclus' iodoform salve, which did not survive, and the *Cbl. f. Chir.* agrees with this opinion (November 13).

Bromid of Ethyl la Hysteric Aphonia.—Arslan reports five cases of hysteric aphonia in women treated with success by bromid of ethyl. The patients were rapidly anesthetized with full doses (10 g.) of the drug and as soon as they were partly insensible, it was suggested that they shout loudly their name, count numbers, etc. The results obtained by the method were satisfactory. In four of the cases there was evidence of disease in the nasopharynx. In three cases influenza was an exciting factor.—*Gazetta degli Ospitali*.

Improved Local Anesthesia.—Operations on fingers and toes, ingrowing nails, paronychia, etc., are the most difficult to anesthetize with the Schleich method, and yet they are the most frequent in general practice. Oberst's method is simple and effective for these cases. The finger or toe is first raised to expel the blood, and the central end, as close to the field of operation as possible, is wound once or twice with an elastic cord, the ends not tied but held with a clamp. Cocain is then injected in the four sides of the finger, directed toward the tip, just below the ligature. The anesthesia is complete in three to ten minutes, tested with a prick, and lasts as long as the circulation in the part is arrested. This method has been followed at Breslau in 124 cases of the kind with such satisfactory results that Honigsmann recommends it warmly in the *Cbl. f. Chir.*, December 25.

Treatment of Hemiplegia with a combination of passive gymnastic, baths and go cart. Huchzermeyer of Oeynhausen advises commencing the treatment promptly, not waiting for complications to develop. He applies it to hemiplegia without regard to the etiology. Commencing with passive exercises of the affected and also of the sound members, half an hour twice a day, stretching, twisting, turning, etc., until every muscle has had its due share of gentle exercise. He considers electricity and massage superfluous in many cases and injurious in others, but supervises the diet and gives four or five salt baths a week at 26 to 27 degrees R., which he considers a most important factor in the treatment. The patient often feels his first spontaneous movement as his members are buoyed up in the dense salt water. The same effect on a larger scale is obtained by a large go-cart, such as is used to teach children to walk, which holds the body in an upright position and allows the patient to swing his legs with the slightest effort of the muscles. The patient recovers under this treatment with remarkable rapidity and completeness.—*Deutsche Med. Woch.*, January 6.

Traction of the Tongue in Apparent Drowning.—A report was recently published in *La Tribune Médicale*, which appears to illustrate the value of traction of the tongue in the restoration of the apparently drowned. A boy fell into one of the docks at Havre, and was not recovered till he had been immersed fully five minutes. He was quite unconscious when brought to land, but a custom-house officer at once proceeded to perform artificial respiration by Laborde's method (rhythmic traction on the tongue), while other attendants rubbed him vigorously and blew air into his mouth. In half an hour signs of life reappeared in the form of respiration and a few moans. He was quite two hours longer before completely recovered. Our contemporaries consider that the fortunate result was mainly due to the tractions on the tongue, and with Dr. Gilchrist of Nice, who has called our attention to the report, suggests that it should be made widely known through the lay press that traction on the tongue repeated regularly fifteen times a minute, is a highly efficacious treatment in many cases of apparent death from asphyxia.—*Brit. Med. Jour.*, January 29.

NEW INSTRUMENTS.

AN ELECTRIC STERILIZER FOR INSTRUMENTS IN EAR, NOSE AND THROAT PRACTICE.

Read by title at the Tri-State Medical Society, Louisville, October, 1897.

BY W. SCHEPPEGRELL, A.M., M.D.
NEW ORLEANS, LA.

The necessity of sterilizing all instruments for surgical operations has been so thoroughly instilled into the minds of medical men that we rarely find a surgeon who does not give careful attention to these details. Many forms of sterilizers have been suggested for preparing instruments for surgical operations, and the majority are of more or less practical value. A subject, however, to which the same amount of attention has not been given, is the preparation of instruments in ordinary use in office practice. It is otolaryngology this refers especially to nasal and oral speculums, tongue depressors, applicators, etc. Each of these may be the means of carrying infection, unless the same attention is given as in the preparation of instruments for surgical operations.

A probable reason why more consideration has not been given this subject is the difficulty of arranging a suitable apparatus in a private office without the disagreeable effects of the heat and odor arising from the sterilizing process. Alcohol and gas lamps each have an objection in this connection. For the purpose of facilitating this matter I have recently devised an electric apparatus, which may be used not only for preparing instruments for operations, but more especially for sterilizing those in ordinary use. As this method obviates the odor from the products of combustion from oil, gas and alcohol lamps, and the inconvenience of using these where there is a current of air, it has displaced all others in my office.

A vessel of two quarts capacity is used, the heat being obtained from fine German silver wire at the bottom of the vessel, as in electro-culinary utensils. In this way boiling water may be obtained in a few minutes.

In this vessel (A), when used for sterilizing, a wire cage (B)

Schepppegrell's Electric Sterilizer.

containing the instruments is lowered into the vessel and left sufficiently long to become thoroughly sterilized. A smaller cage (C) is made for applicators. All metallic instruments used in the office may be prepared in this manner and may be made thoroughly aseptic.

In regard to the economy of this method, it has been shown by James S. Stevens and Burton S. Lanphear (*American Electrician*, September, 1897), that if electric energy can be furnished for fifteen cents per kilo watt-hour, which is believed to be slightly in advance of the average rate, the use of the electric heater is about 30 per cent. cheaper than the commercial (95 per cent.) alcohol for the kind of work for which these heaters are designed.

THE

Journal of the American Medical Association

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, FEBRUARY 26, 1898.

THE ANNUAL MEETING OF THE TRUSTEES.

The Trustees met in annual session, according to the regulations, February 15. All the members were present and the usual routine matters disposed of.

The affairs of the JOURNAL have been very prosperous this year as compared with former years. The circulation has greatly increased, and the finances of the ASSOCIATION have never been in better condition.

The Board adjourned to meet in Denver on Monday, the day before the meeting of the ASSOCIATION. The formal announcement of the special train will not be made until the question of rates by the railroads shall have been definitely settled.

Among other items of general interest to the ASSOCIATION may be mentioned that the Trustees authorized the engaging of a special JOURNAL TRAIN from Chicago to Denver. A committee was appointed to have charge of the same, consisting of the Editor of the JOURNAL and Dr. TRUMAN W. MILLER, with such assistants as they might select from the members of the ASSOCIATION. It was decided that some features of former trains, which have been considered objectionable by many, will be eliminated.

DECREASE OF DEATH FROM CONSUMPTION.

A recent issue of the JOURNAL (Feb. 5, 1898) contained thirty-five pages of matter on the subject of pulmonary phthisis, contributed by nine different writers, scattered from the Atlantic to the Pacific coasts, and during the past decade an enormous amount of more or less valuable similar literary effort has been devoted to the "great white plague." Since the publication of this last batch of papers the JOURNAL has

undertaken to ascertain the effect of this agitation during the last ten years, and the results of the inquiry are decidedly reassuring, at least as to the disease in urban populations.

Roughly stated, twenty principal cities, having an aggregate population of about seven and a half millions (7,478,506), in 1888, had nearly twenty-five thousand deaths (24,708) from consumption in that year; in 1897 the same group of cities, with an aggregate population of nearly ten millions (9,971,341), had a little more than twenty thousand deaths (20,161) from this cause. In exact percentages and per milles the following are the figures: Death rate per 10,000 of population from consumption in twenty cities, in 1888, was 33.03; in 1897 it was 20.21; decrease in death rate 38.8 per cent. Actual decrease in number of deaths, 4547. Actual increase in population, 2,492,835; per cent. of increase in population during the decade, 33.33.

In four of the reporting cities, namely, Minneapolis, St. Paul, Denver and Omaha, there is an actual and relative increase—due, as to the first three, to the increasing number of imported cases, concerning which Health Commissioner MUNN of Denver estimates that 85 per cent. of all consumptive patients in that city are exotic. Among the remaining sixteen cities the most notable reductions are Buffalo, 46 per cent. decrease; Cincinnati, 44 per cent. decrease; Philadelphia, 43 per cent. decrease; New York, 30 per cent. decrease; Brooklyn, 28 per cent. decrease; and Chicago, 24 per cent. decrease.

Of those who assign causes for this decrease, Dr. BENJAMIN LEE, health officer of Philadelphia, gives the following: "First, improved pavements; secondly, improved drainage; thirdly, generally improved sanitary condition of small streets and alleys; fourthly, the diffusion of information by the Pennsylvania Society for the Prevention of Tuberculosis; fifthly, notification by physicians and disinfection of premises, both prescribed by the City Board of Health."

New York tersely ascribes the result to "clean streets, cattle inspection and treatment of tuberculosis as infectious." Dr. S. H. DURGIN of Boston, to "better care from increased knowledge, better isolation, clothing and shelter, greater cleanliness of person and environment." Dr. MAX C. STARKLOFF of St. Louis to "education of the public to appreciate its contagiousness, observance of health department notices against expectoration in public places, and fumigation of premises where death has occurred." Dr. J. M. WITHROW of Cincinnati says: "The decrease is largely due to isolation of consumption patients in hospitals and the practice of sending all city hospital consumptives to a special isolation hospital in the country." And Dr. W. C. WOODWARD of Washington, D. C., thinks it is due to "improved modes of living."

To all of which, and much more of the same sort, the JOURNAL begs leave to add a factor entirely and somewhat naturally overlooked by the health authorities, to wit, the earlier recognition of the disease and its improved and more successful treatment by the medical profession. This factor will undoubtedly account for a large share of the apparent reduction shown in the foregoing figures—a reduction which, it is to be borne in mind, is "apparent" to the extent that they deal only with urban populations and take no note of the increasing numbers of consumptives who are sent away and die in sanatoria, health resorts and elsewhere.

THE "MICROBES" OF RHEUMATISM.

The popular or prevalent theory of the nature of acute articular rheumatism may be assumed to be, at the present time, that of its bacterial or infectious origin. The exact microbe which causes it has been so far unknown, and there may yet be in the minds of some a reservation of doubt as to the above stated pathology. The fact that acute rheumatism is not unknown or infrequent in the polar regions, where NANSEN is said to have suffered from it, may not be much of an argument against this origin of the disease, but it suggests at least a relationship to other diseases that are prevalent in Arctic climates and that are more generally attributed to irregular or morbid metabolism in the system than to living germs from without. The various bacteria, that have been credited or suggested as producing this disorder, by LUCATELLO, SAHLI, LEYDEN and others, have not been generally accepted as having such function by those best qualified to judge, and it has commonly been relegated to the large class of presumably or more or less certainly infectious diseases of which we are yet ignorant of the inciting germ.

The most recent researches in this special direction are possibly a little more suggestive and promising than any that have preceded them. In the November issue of the *Annales de l'Institut Pasteur*, M. ACHALME publishes an account of an organism that he has found most abundantly in the autopsies of two fatal cases, but also in the blood of living subjects of rheumatism and which from its behavior in control experiments and cultures appears to be possibly connected directly with the disease. It was a thick rod-like bacillus, not dissimilar to that of anthrax, exclusively anaerobic, requiring for its culture a very complete vacuum, staining readily by anilin and by the WEIGERT and GRAM methods. Its cultures give rise to lactic acid and an odorous mixture of acetic, butyric and propionic acids; its development was arrested by very small amounts, less than those required for other organisms, of sodium salicylate.

When inoculated into guinea pigs it caused the characteristic symptoms, infiltrations, pleural effu-

sions, etc., of rheumatism, the animals succumbing in twenty-four to thirty-six hours. In rabbits endocarditis and pleurisy closely resembling those in the human subject followed the injection of serum from inoculated guinea pigs. The bacillus readily associated itself with other microbes, especially streptococci, and seemed to favor their penetration into the organism.

The discovery of ACHALME is to a certain extent corroborated by two later investigators, M. TREBOULET and COYON, who reported their results to the Société Médicale des Hôpitaux, Paris, on December 24. They made a special search for ACHALME's bacillus in a number of cases of rheumatism, and in every patient examined they found a special form of diplococcus, oblong, always in pairs, about two microns in diameter, to a certain extent anaerobic, and not decolorized by GRAM's method. In two very severe cases of rheumatism, however, they found ACHALME's bacillus, and also in certain autopsies, associated with their own diplococcus. According to their observation the bacillus appears to be only associated with the severer forms of rheumatism, while they suggest that their own discovery, the diplococcus, may be the common microbe of the disease.

Whatever may be the estimate of the importance or value of these researches, they are in the right direction, and should lead to still further studies upon this subject. There are relations between acute and chronic rheumatism also that require elucidation, in fact the whole subject is a broad enough one to engage attention for some time to come; there is not much danger of the immediate exhaustion of the field for research in this special direction. There are other bacilli that produce lactic acid and that succumb to the salicylates than that described by the French author, but his discovery has enough special characteristics to suggest a possible connection between it and the severer manifestations of acute rheumatism. The diplococcus found by the other observers may or may not be found later to be directly connected with the lighter phases of the infection: it certainly deserves a further study as to its reactions and development. The lead thus opened will undoubtedly be followed up and it is to be hoped will before long give us some more definite knowledge than we now possess of the real nature of the rheumatic poison.

THE FREE MEDICAL AND SURGICAL TREATMENT OF THE WELL-TO-DO IN MICHIGAN UNIVERSITY.

Since their establishment the Clinic and University Hospital at Ann Arbor have, as a rule, treated all who applied. Occasionally a particular professor would object to treating a notoriously rich person, but no rule has been adopted. Moved, doubtless by

the protests of the profession and their own sense of equity, the medical faculty requested the Board of Regents at a late meeting to exclude all well-to-do people seeking admission to the University Hospital. The board has the matter under consideration. It is reported in the public press that the majority are opposed to such exclusion of the rich. They hold that the hospital is for teaching students of the medical department, and that a millionaire makes just as good a subject for teaching as a pauper; that he pays taxes to the support of the hospital, and so has a right to the free services of the University Hospital staff.

This view of their duties is quite at variance with that held by the people who elected the regents. The latter expect the regents to conduct the University Hospital and Clinic in such a manner as to teach the medical students practical medicine and surgery, without disturbing the interests of any class of citizens, and without promoting discord between classes, or antagonism to the university based upon unjust discrimination.

First it is creditably stated that the University Hospital would be full from the ranks of the poor, if only the rich were excluded. Hence there is no need to admit the rich for the purpose of augmenting the size of the clinic. It is also creditably stated that the character of cases presented by the well-to-do, differs in no essential respect from those of the poor; all are of the chronic order admitting of transportation over long distances, as cases of cataract, chronic surgical injuries or diseases. Hence on the ground of quality of cases there is no reason for the admission of the rich to the Hospital for the benefit of the students.

But the regents were chosen to conduct the Hospital for the benefit of all the people of the State, so that it is pertinent to inquire respecting this benefit. An illustration or two may aid us to understand the effect of free treatment of the rich at the University Hospital. A friend of the writer living in western Michigan told him that for years the only way he could keep any case of cataract, or other operative case on the eye, was to figure out the railway fare to and from Ann Arbor and the cost of two weeks board at three dollars per week, and offer to do the operation for the resultant sum. Before he adopted this rule all well-to-do people went to the University Hospital. The fact of the free treatment of the rich at the University Hospital, was the club used by the rich to compel his working at utterly inadequate prices. Even those who had no idea of going to Ann Arbor used this club of the Free University Hospital to compel him to meet the competition of that institution, to support which he was taxed. He observed that these same people developed the habit of beating others on all possible occasions, apparently because they had beat the State out of services for which they were able to pay. He also said that there was much

grumbling on the part of persons of moderate means, because their rich neighbors got for nothing services for which they paid—grumbling directed against the University.

Another practitioner in a different portion of the State would not adopt this plan; as a consequence nearly all well-to-do operative cases left him and were treated at the Free University Hospital. What work this man did, he insisted on being paid for in a reasonable manner; the result to his practice was evident. The cases that were able to pay largest fees went to Ann Arbor and were treated for nothing.

These two practitioners are types of all who treat chronic medical or surgical cases, and they illustrate the effects of the Free Hospital service at the University. The rich have been encouraged to try and get something for nothing, thus engendering a spirit hostile to the best citizenship. The poor have been crowded from the place and service intended for them, and so wronged. While persons of moderate means who regularly pay their medical advisers, are dissatisfied with being also forced to pay taxes in support of a hospital, physicians and nurses, for the free treatment of their rich neighbors. It is obvious that the Free University Hospital undermines the financial support of the medical profession both directly and indirectly; directly, in that their own rich patients are lured away by the cheapness of the Hospital; indirectly, in that many well-to-do people by the threat of going to the Free Hospital, compel services at rates far lower than rates for such services in regions distant from the influence of the University Hospital. It is thus evident that the value of the University Hospital would in no respect be impaired by restricting admission to those unable to pay for medical services. The quantity of patients would be as large as it could accommodate, and the quality all that can be secured in a small town. Therefore the interests of the Hospital would be advanced by restricting admission to the poor.

It is farther evident that the interests of rich, poor and those in moderate circumstances unite with those of physicians in demanding that the University Hospital be closed to those able to pay for medical services.

It is hoped that the Board of Regents will regard their obligations to the Hospital, to the University, to all citizens of the State and heed the request of the Medical Faculty.

THE APOTHECARY.

Our editorial on the "Passing of the Apothecary" seems to have provoked considerable discussion, some in concurrence and some adverse, and we have been "roasted" with great unction in some pharmacy journals. It was not intended to belittle the profession of pharmacy but merely to show the trend of the times. One of our correspondents (in January 15

issue), in trying to show that we are mistaken, confirms much that we said but blames it all on the physician. "We are compelled to load down our shelves with a dozen makes of pills, etc., merely to please the physician." And he concludes by saying that "the lot of the pharmacist is not a happy one" because the physician allies himself with the manufacturing chemist to enrich him and help himself.

This is the very point. Why does the physician ally himself with the manufacturing chemist? Why do men standing at the topmost rung of the profession agree to become consulting therapeutists for commercial concerns? Why do chemists of international ability become the attachés of these establishments? Is it commercialism that is at the bottom; is it according to an industrial evolutionary law? We did not answer these queries, we simply mentioned the fact as it exists. And while there are many able, intelligent and exceptionally well educated men in the profession of pharmacy, some better educated than many physicians, we still maintain that, in certain cities at least, there are numerous drug stores conducted by individuals who have studied a few months or more and passed a haphazard examination, and who conduct a variety store rather than an apothecary shop, who are merely agents for the wholesale houses. We know at least a half dozen stores in one large city, run by the wives of young men who themselves one year before were workmen in some other trade. While there are probably more college trained men in the profession of pharmacy today than ever, yet we affirm that today it is possible as it never was before, for a person to dispense medicine in a large city who does not know how to make a tincture, a pill, a suppository or any of the ordinary preparations called for. That these things are done for him, and apparently satisfactorily, by large concerns whose tendency is to grow larger and to embrace more and more the work of the individual pharmacist. It is true that the department stores do handle toilet articles, etc., and even patent medicines and quinin pills, but glance into the windows of the metropolitan fashionable drug shop and see what importance is given to bric-a-brac, to the *bar*, to soaps and perfumes and candies! We regret the departure of him of "the mortar and pestle," and if it be true, as our correspondent says, "that better days are in store for him," we congratulate him. We feel, however, that this thing is not of the physician's doing, though he is drawn into the struggle, but that it is the result of a chain of circumstances peculiar to the time, against which neither the pharmacist nor the physician can battle successfully.

THE DISPENSARY WAR.

In nearly all of the large cities the evils of free dispensaries are recognized, and the great question is to know what to do, how to abandon them and how to

end their pauperizing influences. In the city of New York two parties are gathered in battle array. One would like to restrict the present free practice in dispensaries and stop the organization of new ones; the other would enlarge the scope of this work, and permit new places to give free treatment. The college teachers and post-graduate schools are very active to keep up the dispensaries, and the general practitioner realizes their danger to himself and the community. The issue is to be settled by a bill prohibiting dispensaries except under certain general restrictions, now pending at Albany. At this distance it is difficult to understand how any defenders of the present dispensary system can make a reasonable plea for their continuance on their existing basis. The profession have fallen into a low commercial level of giving gratuitous services, at all times and places, and have lowered themselves and the recipients of their charities. No other profession has pursued such foolish ways of work for the community, and as a result there is suffering. The blatant quack comes into a community and is paid for his pretensions. The poor always have money to reward him, but the well trained physicians must give their knowledge and skill for charity. The war should be to revolutionize these senseless delusions and not to perpetuate what is so clearly a wrong. We all unite in calling for a higher grade of medical preparation, and why should there not be an equal union of sentiment in raising the work of the profession to at least a common sense basis of reciprocity and dignified recognition of the value of such services. It is to be hoped that the good sense of the metropolitan physicians will prevail over the narrow policy of continuing an abuse fatal to all that is just and equitable.

CORRESPONDENCE.

Dr. McLean's "Personal Observations in Pulmonary Phthisis."

DENVER, COLO., Feb. 12, 1898.

To the Editor:—I have just finished reading this excellent paper in the February 5 issue of the JOURNAL and I feel like congratulating the author on writing the best article that has appeared for some time on the *prevention* and treatment of consumption. It is *prevention* more than *cure*, because once the conditions of imperfect aeration of the lung apices and the peripheral or terminal laxity of pulmonary blood vessels exist, which constitute the *gist* of this unanswerable argument, and the preventive warfare of the individual must be constant thereafter in order that health may be maintained. We seem (only *seem* in any case) to neglect these preventive means in treating and writing of the serious and advanced lesions which predominate in the class of tubercular cases which come under observation in this sanatorium State. It gives me pleasure to endorse these measures which are preventive. They are applicable alike everywhere, but especially in low damp climates where the dangers are greatest. Prevention antedates and then goes along with treatment, of which it is the major part any way. This idea seems to emphasize the importance of Dr. McLean's earliest "diagnostic symptom," or the "gravitation

cough," as he calls it. His idea is unique and its explanation plausible with regard to the early hacking cough or clearing of the throat on retiring at night. It may be the first sign-board on the road to phthisis and therefore a good warning for the rest of us to review our own experience in recognition of it. To take an N. B. of so early a symptom is to be forewarned of the trouble to come. It beats the bacillus of tubercle as to time, for all that we now know, and fixes it as an after episode of an already established condition.

The treatment indicated is in confirmation of all we have been preaching for these past twenty-five years in favor of exercise and high altitude climate. Especially is it gratifying to me to see such a confirmation of the need and such a proof of the utility of the "In- and Exhaler," advanced by one who had probably never seen this little pocket device (descriptions of which will be sent to any one applying to the Denver Surgical Instrument Co.). I infer this unfamiliarity with the In- and Exhaler because in the claim advanced for "mechanical expansion" of the lung periphery and bronchi, as a possible substitute for living "at an altitude that gives immunity against phthisis." McLean says: "Among the various ingenious methods which have been devised I could find none that were free from objection, as they almost invariably increase the heart's action, which opposes rather than helps the purpose of their use." The ease with which this "mechanical expansion" can be accomplished *at will* by the total of the one to two hours in each day's interrupted use of this In- and Exhaler, is apparent to even a lay observer. It is evident, too, that this is without any undue disturbance of the heart's action whatever, because of the *adjustibility* of the instrument's two valves. Special reference is made to the *exit valve* because it is only during *expiration* (not with *inspiration* as in faulty methods usually employed) that this "mechanical expansion" can be obtained. The most delicate bedridden invalid can lie near a window and breathe in, through a tube attached to this inhaler and extending out doors, the cold lung-expanding air, medicated to suit with mentholated, formalined, eucalyptized, etc., vapor, and according to his or her strength compel its entrance into the finer tubes and vessels of the lungs. The heart meantime is only helped in its action, for the limit of the instrument's use is suggested to be the reddening of the face, *i. e.*, the congestion of the body's periphery by the driving outward of the blood from the impeded and paralyzed pulmonary vessels. Dr. McLean's endorsement of the pneumatic cabinet, and then his criticisms of its impracticability and cost furnish an excellent recommendation for this convenient little pocket device, easily made adjustable to every one's needs.

I may attempt to answer the question propounded, where the author instances Reynard's experiment proving that a rabbit confined for a month in an atmosphere reduced in pressure to the equivalent of that at 6000 feet elevation, developed the same blood changes as in "rabbits transferred from sea level to a climate at 6000 feet elevation," namely, "Would the same changes in the blood have been produced in an animal breathing the same rarefied atmosphere of 6000 feet with the density of atmosphere pressing upon the external surface of the body as exists at the sea level?" That is, was the improvement due to the rarefied air alone which the animal breathed, or was it due to this combination with the diminished air pressure upon the surface, or was it due to the decreased pressure on the external surface alone? I should say that you can not disassociate the dual effect in explaining the total benefit invalids receive in resorting to a high altitude. On the one hand you have the increased pressure (Dr. McLean's "mechanical expansion") due to the positive necessity to breathe a fifth more air to get the same amount of oxygen at a mile above the sea; and on the other hand you have the *suction* of the blood from the thorax and closed areas toward the periphery.

This latter is similarly explained, but the *reverse* of the congestion of the spinal cord and proportionately of all partially closed areas (as in the coverings of the brain) manifest in the cascous disease. This is the effect produced in workmen subjected to toiling in an atmosphere of greatly reduced pressure.

But the internal increased pulmonary air-pressure and the external diminished pressure of a high altitude atmosphere may be variously substituted for and varied in their proportionate effects by mechanical devices and systems of exercise. For instance, in the pneumatic cabinet, a person breathing the outside air, with the air around him reduced, has the proportionate drawing of the blood into his peripheral vessels correspondingly exaggerated according to the diminished pressure reached in the cabinet. On the other hand, exercise can be chosen, as Dr. McLean has so well shown, which will increase the "mechanical expansion" of the peripheral air cells and tubes of the lungs, with no dependence at all upon the suction effect mentioned of a circumambient atmosphere reduced in pressure. The inhaler referred to, if faithfully used, can do this. In fact, I believe the proportionate manifestation of tuberculosis in the lungs, as compared with other organs, would be greatly lessened and a good percentage of consumption be prevented if there existed the determination and will power, especially among the young, to persistently practice mechanical expansion by this, or possibly by some equivalent method. To use the words of Dr. McLean, "the price of health is vigilance and effort. If the phthisical patient would live and be healthy he must work for it, and in the way I have indicated or by some similar method, or he will miserably perish, notwithstanding he may swallow all the drugs in the dispensatory and be injected with all the serums and specifics, so-called, which are now obtainable. The expansion method of treatment is *nature's method* and is helpful in every stage of the disease, except where there is active hemoptysis from organic changes."

Let me urge the thoughtful perusal of Dr. McLean's paper.

CHARLES DENISON, M.D.

Prescribing Ready-made Compounds.

CHICAGO, Feb. 9, 1898.

To the Editor:—In the prevention and successful treatment of disease our science culminates and becomes an art. Therapeutics, the philosophic adaptation of remedial agents to the correction of pathologic conditions, the cure of disease in the human organism and its restoration to that physiologic equipoise we dominate health, is the full consummation of science and art. No one unfamiliar with physiology and pathology, pharmacodynamics and therapeutics can prescribe for any disease in a scientific manner. Therapeutics must be regarded as first among the principles of scientific medicine by learned and cultured members of our profession. The adaptation of means to the accomplishment of wisely purposed ends in the practice of medicine and surgery, implies much as to acquirements and knowledge? Every case is stamped with an individuality by which it is differentiated from all others. We find special perversions of functions and pathologic tendencies having relation to the assemblage of abnormalities presented by the case. The educated physician addresses himself to the task of securing a mastery of every factor and of meeting every indication essential to final victory.

When men of rare endowments and an encyclopedic fund of knowledge recognize the necessity for clear definite information and long investigation before authorizing the use of remedies in many cases, how can we reconcile the conduct of many with the obligations imposed, who simply order some nostrum, ready-made formula or trademark preparation? How can the manufacturing man even though he be a pharmacist, prepare such a combination of drugs as to adapt them to the cure of the hundreds of diseases met with each year? Drugs and

chemicals are modified in their action upon the human organism by age, sex, habits, idiosyncracies, temperament, constitutional taints (acquired or hereditary), avocation, climate, condition of the system at the time of administration, etc. Men who use these ready-made cure-alls forego the exercise of those powers of ratiocination in the adaptation of remedies to each individual case, according to its peculiarities and needs, which ever and always distinguish the learned from the ignorant. They insult the educated pharmacist by presuming that he could not prepare any combination required by the formula they wrote: and they only too often make clear the fact that they are incapable of originating such a combination of ingredients as the complexities of the case demand.

Prof. Geo. B. Wood, the scholar, scientist and author, in his great work published in 1860, entitled, "Therapeutics and Pharmacology," uses this language touching ready-made formulæ:

"It leads to an indolent reliance on mere authority by sparing the trouble of thought, and greatly conduces to an empiric and routine practice, neither creditable to the physician nor profitable to the patient. The author has preferably sought to give principles, by which the physician himself may construct formulæ suitable to each special case. He has endeavored to point out in reference to each medicine the peculiar circumstances which render its use appropriate, and the modification in doses it must undergo to adapt it to the varying circumstances of different cases, or the same case at different times. He has also called attention to the medicines with which in each special case it may be appropriately combined to aid or qualify its action. With this knowledge and that of the pathologic conditions to be corrected, the educated physician will be qualified to form much more appropriate associations or combinations of medicines, and to regulate much more correctly the proportions of the several ingredients in correspondence with the indications than any formulary can possibly do for him; nor can any medical man be considered educated or duly instructed until he is capable of constructing such formulæ for his own use and purposes."

The educated physician and educated pharmacist have delicately allied duties in their relations with the public, and no educated physician should allow his prescriptions to go to a mere trader in drugs; nor should a pharmacist ever commend an illiterate, uneducated physician. We should stand in an honorably helpful relation to each other and strive to excel in the breadth of our attainments, the excellence of our work.

W. T. AKINS, M.D.

Appendicitis: Comments Upon Dr. Haughton's Letter.

NEW YORK, Feb. 15, 1898.

To the Editor:—In the JOURNAL for Feb. 12, 1898, I find a reply from Dr. Haughton to Dr. Carstens which seems to fail to comprehend the subject of appendicitis in just the proper way. Perhaps there is no subject in medicine more thoroughly understood than that of appendicitis. The pathology, etiology, symptomatology and anatomy are all so completely recorded by our authorities that it is only the men who are too busy to read the works of authorities who imagine that there is still much room for discussion upon the subject. It has been demonstrated and recorded that the operative death-rate in acute and in chronic appendicitis without abscess, is only a fraction of 1 per cent. at the hands of several of our American surgeons.

It has been demonstrated and recorded that the men who represent diagnostic acumen of the highest order are powerless to make a prognosis about the outcome of any given case of appendicitis. It has been demonstrated and recorded that so large a proportion of "cured" appendicitis patients carry concretions and mucous inclusions and tubercular foci, and entozoa, and chronic abscesses that the eventual death-rate in ap-

pendicitis is not likely to show less than 25 per cent. death-rate under any form of medical treatment.

Curiously enough the reports of long lists of cures under medical treatment have seemed to be rather dishonest in their nature, and they bear the ear marks of a spirit of controversy rather than of an interest in pure science. A medical report on appendicitis cases should have several clearly defined features. A statement about the length of time of observation, of number of deaths, of number of occurrences of acute symptoms, of interval palpation findings, and of the interval condition of general health of each and every patient. I am acquainted with several physicians whose love for truth was so much greater than their love for controversy that they began to get statistics of this sort, but unfortunately for statistics they soon decided that their appendicitis patients must be operated upon promptly.

Apparently every physician who publishes long lists of appendicitis cases cured by medical treatment knows in his heart that he is doing wrong. When he congratulates a patient on getting well without operation he knows in his heart that that patient is very likely indeed to be carrying at least a mucous inclusion, and that he is not a cured patient. It is almost incomprehensible that men whose duty it is to devote their lives to the relief of suffering should be so fond of controversy that they can not be honest to themselves, or to their sacred profession, or to the people whose precious lives are entrusted to their care. Dr. Haughton has quoted one writer who published a list of appendicitis cases cured by medical treatment. I have challenged this writer's report, and although he has privately stated that he will not look up his cases, and that he will not tell the profession what has become of them, I shall keep trying in various ways to get him to do it, and I hope to get a general report in the interest of science before the matter is allowed to rest. I may have to bear a great deal of personal abuse and may be put to much trouble, but it is all for the sake of humanity, and that makes one's labors seem light. Clouds are coming over many a happy home in this fair land on this very day because the family physician who conscientiously tries to do the very best thing for his appendicitis patients is misled by controversial reports from physicians who do not realize that their irresponsible influence is carrying death in its trail.

ROBERT T. MORRIS, M.D.

Appendicitis.

MARIETTA, OHIO, Feb. 15, 1898.

To the Editor:—I have been interested for some time past to learn how it happens that some doctors have so many cases of appendicitis, upon which they find it necessary to operate. Is it not a fact that most of the so-called cases of appendicitis are primarily impaction of the cecum and colon, which by proper medication can be relieved and avoid the operation? These thoughts come to my mind from the fact that I have been in a very active general practice, medical and surgical, for the past fifty-four years, and have never had but one case that needed operation, and that one in my early service, and far advanced. I lanced it and he soon made a good recovery. I think that with those in which I have been called in consultation, I have treated more than one hundred cases without the loss of one, simply by medication. I have no doubt but the vermiform appendix plays its role in all such cases and was placed there for some useful purpose, although we may not fully understand it. I shall in the future as in the past, try medication before operation.

B. F. HART, M.D.

Foreign vs. American Schools.

WASHINGTON, D. C., Feb. 14, 1898.

To the Editor: It is gratifying to note in the columns of the JOURNAL that several correspondents have had the courage

to speak out their convictions as to the supposed advantages of European medical education when compared with those of our own country.

Permit me to say that my personal experience warrants the full corroboration of the statements made by your correspondents. Familiarity with the teaching of the medical schools in our Eastern cities, and frequent trips across the Atlantic the last twenty years, during which I studied at the principal European medical centers, have afforded ample opportunity to make comparison which, without any spread-eagleism, I am forced to say is greatly in favor of my native land. Just why any true American should go into ecstasies over anything German has always been a puzzle to me. While there are many individual Germans whom I respect and admire, candor compels me to say that after much travel around the globe Germans, as a class, are the rudest people I have ever met, and beyond beer and music I found nothing to admire in a country where most things partake of the cheapness and mediocrity of the imported articles labeled in *Deutschland gemacht*. During my stay in that garish but most dull and unattractive city, Berlin, shortly after the Franco-Prussian war, I was constantly taken for *ein Britisher*, and on witnessing an operation it was a common thing to be told that "they do it better in your country," little knowing that I was from the land of the tabooed pig and apple.

Though devoting a year to the study of German medical nomenclature alone before going abroad, I found it impossible to seize more than a general sense of the lectures attended. The study of German, in view of the enormous growth and great spread of English, is a waste of time only equaled by the *German medical journal disease*, or the absurdity of expecting to find in that country what exists in greater perfection in New York, for instance. Indeed, medical education has so advanced in this country of late that it is safe to predict that before many years Europeans will come here for study.

Of course I do not wish to imply that nothing is to be gained by going abroad. If the medical man really wants to learn he will find London, Paris and Rome the best places, and if interested in neurology, psychiatry or criminal anthropology, he will find Italians in the foremost rank. Every medical man who can afford it should visit Europe, not so much with the expectation of professional benefit as for that accruing from attrition with other minds, the wiping away of numerous cobwebs of prejudice, and the still stronger reason that he will return to his native land a better American.

IRVING C. ROSSE, M.D., F.R.G.S.

Leprosy in Norway and America.

BERGEN, NORWAY, Feb. 1, 1898.

To the Editor:—Allow me to make some corrections of Dr. Caldwell's article in the number of December 18, which you have sent me. Dr. Caldwell says that in our hospitals for the confinement and treatment of lepers were "domiciled over one thousand unfortunates afflicted with that terrible disease." From where or from whom Dr. Caldwell has obtained this information I can not imagine, for we had last summer not more than about three hundred and fifty lepers in our institutions. Later on Dr. Caldwell says that "I, in my visit to the United States found three cases in the hospitals in Chicago and twice as many in New York, as well as encountered several cases of true leprosy upon the streets of each city, all of whom were treated for lupus, syphilis or some other form of skin disease." I regret if any of my Norwegian colleagues has given such information to Dr. Caldwell. The truth is that in Minnesota I found one case and in the City Hospital in Chicago one case, not of leprosy treated for syphilis, but of syphilis diagnosed as leprosy. Now this is not to be wondered at, when the doctors have no acquaintance with leprosy. You will allow me to tell

the incident in the City Hospital in Chicago, where I went accompanied by my colleague, Dr. Sandberg of Chicago. A young American doctor led us to the patient, who was a Dane. I saw at once that the man had no leprosy and asked him in Danish, "When did you get your chancre?" "Seven or eight months ago," replied the man. The young American doctor, who understood the word chancre, I suppose, said: "Oh, sir, he does not understand that." "Certainly he understands," said I. "He had his chancre eight months ago." "Oh, dear me," said the young man.

In the streets of the cities I never saw a leper, and I account for disease not spreading from the leprous immigrants of Wisconsin, Minnesota and Iowa by the cleanliness of the people everywhere. I said then and I say still: The first thing a Norwegian peasant, who is not cleanly, learns in America is to wash himself, and that does great credit to American customs. While writing you I will take the liberty to say some words of Dr. Ashmead's letter in the same number. I will not take up a discussion of the Leper Conference in Berlin. I will only say that I still never have seen an instance of "melancholia of leprosy." This affection is a discovery of Dr. Ashmead, but I regret to say that neither I nor anyone else in Norway has any idea of the existence of such an affection. One may meet with lepers who are melancholic, of course, but generally our lepers are of the same mental disposition as other people, and remarkably seldom we see a depression of their good humor, in spite of the disease; the reason is that the brain is never affected in leprosy, and one sees often enough people keep their good spirits in spite of even more fearful diseases than leprosy. I am, sir, yours respectfully,

G. A. HANSEN, M.D.

The Alleged Castration of Squirrels.

HUDSON, OHIO, Feb. 8, 1898.

To the Editor:—In a recent JOURNAL Dr. Taylor has a communication with this heading "Do adult squirrels castrate each other?" A better heading would be "Do any squirrels castrate each other?"

In Vol. iii, page 646 of Owen's "Anatomy of Vertebrates" you will find a description of the male organs of the rodentia. Among other things he says: "The testes undergo a periodical increase of size and change of position, passing from the abdomen into a sessile scrotum and being again retracted, after the rut, within the abdomen." This change of position involving the disappearance of these glands, which are very conspicuous during the rutting season, has given origin to the belief that the males were often castrated. The Doctor notes a very significant fact that this supposed castration by another squirrel leaves no visible scar. If a surgeon will perform the operation with his sharpest knife he will leave a scar that will bear witness to his work. Any one who will carefully dissect one of these supposed emasculated males will find the missing testes within the abdomen so reduced in size as to be easily overlooked.

M. C. READ, M.D.

Physicians Should be Compensated.

PHILADELPHIA, PA., Feb. 18, 1898.

To the Editor:—The editorial in the number of your JOURNAL for February 12 upon the subject of "notification of contagious diseases" is very timely. I have never been able to understand why physicians should be forced to make notification of contagious disease without compensation, as is commonly done in this country. In England physicians are paid two shillings and six pence each time they give notice of a case of contagious disease in their private practice, and one shilling if the case occurs in a public institution. This is provided by law. It seems contrary to fundamental justice, if not to law, that the medical profession should be made to perform labor without compensation, and I have often wondered whether the courts would not sustain a resistance of it.

Respectfully yours, ARTHUR V. MEIGS, M.D.

Advertising in Medical Journals.

SOUTH MCALESTER, I. T., Feb. 4, 1898.

To the Editor:—In answer to an advertisement in the *Tri-State Medical Journal* for December, 1897, I received the following literature:

DOCTOR—DO YOU CURE YOUR GOITER PATIENTS?

I cure all of mine and receive from \$25 to \$50 from each of them. The cost of treating a case will not exceed \$1. Inclose a 2 cent stamp for particulars.—M.D., Lock Box —, Bloomington, Ill.

When respectable (?) medical journals admit such people to their advertising columns it is certainly time to cry halt. We wonder at the imbecility of the laity when they employ quacks, but what shall we say of the members of the profession who are equally guilty, as proven by the enclosed testimonial?

Such journals are more than "particeps criminis," they are the instigators. Some means should be devised to compel these people to either sail under their true colors or return to the ranks of professionalism. Fraternally,

C. A. SHAW, M.D.

ASSOCIATION NEWS.

The Senn Medal.—Those members of the AMERICAN MEDICAL ASSOCIATION intending to compete for the medal offered by Dr. Senn for the best essay on some surgical subject, are requested to forward the type-written copies of contributions before March 1, 1898. Address,

J. McFADDEN GASTON, M.D., Chairman, Atlanta, Ga.

Section on Materia Medica and Therapeutics.—The following papers and discussions have been promised for the meeting at Denver, Colo., June 7-10, 1898:

"Yellow Fever: Its Etiology and Treatment." Discussion by Surgeon-General George M. Sternberg, Washington, D. C.; Prof. John Guitéras, M.D., Philadelphia; Drs. Sollace Mitchell, Jacksonville, Fla.; T. S. Scales, Mobile, Ala.; G. B. Thornton, Memphis, Tenn.; H. M. Bracken, Minneapolis, Minn.; P. E. Archinard, New Orleans, La.

"Aims of Modern Treatment of Tuberculosis." By Prof. Edwin Klebs, M.D., Chicago. Discussion by Drs. Charles Denison, Denver, Colo., and C. H. Whitman, Los Angeles, Cal.

"Serum Therapy of Tuberculosis." By Prof. S. O. L. Potter, San Francisco, Cal. Discussion by Prof. James M. Anders, M.D., Philadelphia.

"The Therapeutics of Pulmonary Phthisis." By Paul Paquin, M.D., St. Louis, Mo.

"Tuberculin as a Diagnostic and Curative Agent, with Report of 250 Tubercular Cases Treated." By C. H. Whitman, M.D., Los Angeles, Cal.

"The Practical Value of Artificial Serum in Medical Cases." By P. C. Remondino, M.D., San Diego, Cal.

"The Use of Remedies in Diseases of the Heart and Blood vessels." By T. Lauder Brunton, M.D., D.Sc., F.R.S., London, England.

"The Mescal Button." By Prof. D. W. Prentiss, M.D., Washington, D. C.

"The Modern Intestinal Antiseptics and Astringents." By William Frankhauser, M.D., New York.

"To What Extent is Typhoid Fever favorably Modified in its Course, Duration, Termination or Sequelæ by the Administration of Drugs?" By Frank Woodbury, M.D., Philadelphia, Pa.

"Strychnin." By J. N. Upshur, M.D., Richmond, Va.

"Methods of Teaching Materia Medica and Therapeutics." By Prof. G. H. Rohé, M.D., Baltimore.

"The Study of Materia Medica and Therapeutics." By H. M. Bracken, M.D., Minneapolis, Minn.

"The Great Therapeutic Importance of a Rational Adaptation of Cathartic Remedies to the Physiologic Functions of the Gastrointestinal System." By E. D. McDaniels, M.D., L.L.D., Mobile, Ala.

"Why the Pharmacopœial Preparations Should be Prescribed and Used by the Profession." By Leon L. Solomon, M.D., Louisville, Ky.

"The Use of Electricity by the General Practitioner." By Caleb Brown, M.D., Sac City, Iowa.

The following have also promised papers, subjects to be announced very soon, together with the day assigned for each discussion and paper:

Drs. J. E. Atkinson, Baltimore; Henry Beates, Philadelphia; T. M. Balliet, Philadelphia; George F. Butler, Chicago; Dudley W. Buxton, London, Eng.; J. Solis-Cohen, Philadelphia; N. S. Davis, Jr., Chicago; P. J. Farnsworth, Clinton, Iowa; J. E. Moses, Kansas City; Prof. Joseph Remington, Philadelphia; Drs. L. E. Sayre, Lawrence, Kan.; H. V. Sweringen, Fort Wayne; E. L. Stephens, Fort Worth.

The Chairman will be pleased to receive and place upon the program subjects for discussion and papers.

JOHN V. SHOEMAKER, M.D., Chairman.
1519 Walnut Street, Philadelphia, Pa.

SOCIETY NEWS.

New Hampshire Medical Society.—The adjournment of the Society to May 30 and 31, 1898, necessitates a change of date, as May 30 is a holiday (Memorial Day); therefore, the annual meeting will be held in Concord, May 26 and 27, 1898.

Atlantic City Medical Society.—The following officers of the Atlantic County Medical Society was elected at a recent meeting: President, W. Blair Stewart, Atlantic City; vice-president, H. C. James, May's Landing; secretary and treasurer, Walter Reynolds, Atlantic City; reporter, W. C. Darnall, Atlantic City; permanent delegate to State Society, Theophilus Boysen, Egg Harbor City.

Medical Society of the State of Pennsylvania.—The next meeting of this society, May 17, 18 and 19, at Lancaster, will be the fiftieth anniversary of the Society's existence. The first day will be devoted to the "Practice of Medicine;" the second to "Surgery;" the third to "Obstetrics." The evening of the second day, will be devoted to an illustrated lecture, by Dr. J. T. Rothrock, Commissioner of Forestry of Pennsylvania, on the "Sanitary Relations of Our Highlands to the State."

The American Pediatric Society is making a collective investigation of infantile scurvy as occurring in North America, and earnestly requests the co-operation of physicians, through their sending of reports of cases, whether these have already been published or not. No case will be used in such a way as to interfere with its subsequent publication by the observer. Blanks containing questions to be filled out will be furnished on application to any one of the committee. A final printed report of the investigation will be sent to those furnishing cases. Signed by the following Committee:

J. P. Crozer Griffith, Chairman, 123 S. Eighteenth Street, Philadelphia; William D. Booker, 853 Park Avenue, Baltimore; Charles G. Jennings, 457 Jefferson Avenue, Detroit; Augustus Caille, 753 Madison Avenue, New York City; J. Lovett Morse, 317 Marlboro Street, Boston.

American Academy of Medicine.—Announcement and preliminary program of the twenty-third annual meeting to be held at Denver, Colorado, on Saturday, June 4, and Monday, June 6, 1898. The meeting will be held in the Brown Palace Hotel, which has been made the headquarters of the Academy, the management having given special rates for the occasion. It is suggested that rooms be secured early, especially if it is intended to remain to the meeting of the AMERICAN MEDICAL ASSOCIATION.

It is planned to hold three sessions on Saturday beginning at 10 A.M., at 3 and 8 P.M. Another session will be held on Monday, at 8 A.M., at which time it is hoped all the business can be completed, affording the Fellows an opportunity to attend the meetings either of the Association of American Medical Colleges or the National Confederation of State Medical Examining and Licensing Boards, which meet on this day. This plan contemplates holding the reunion session on Monday evening.

The following papers have been promised. Several others have written expressing a desire to prepare a paper, but as a definite promise has not been given, it is thought wisest not to

publish their names. The arrangement is alphabetical, and not in the order in which the papers are to be read:

1. Dr. L. Duncan Bulkley of New York, "The President's Address."
2. Dr. Charles Denison of Denver, "The Advantage of Physical Education as a Prevention of Disease."
3. Dr. Thomas C. Ely of Philadelphia, "The Importance of Training the Special Senses in the Education of Children."
4. Dr. J. Edgar Fretz of Easton, Pa., "Some Criticisms on the Questions of the Medical Examining Boards by a Recent Graduate."
5. Dr. G. G. Groff of Bucknell University, Lewisburg, Pa., "The Necessity of Medical Supervision in School Life."
6. Dr. Bayard Holmes of Chicago, "Growth and Strength and its Relation to Education and Medicine."
7. Dr. Henry M. Hurd of Baltimore, "How Much to Educate the Growing Brain."
8. Dr. Woods Hutchinson of Buffalo, "The Muscular Basis of Education."
9. Dr. Edward Jackson of Philadelphia, "The Care of the Eyes During School Life."
10. Dr. Elmer Lee of New York, "The Interdependence of Healthy Bodies and Healthy Brains."
11. Dr. J. C. Lichty of Clifton Springs, N. Y., "The Modern Sanitarium and its Relation to the General Medical Profession."
12. Dr. Charles McIntire of Easton, Pa., "Snags in the Course of the Medical Examining Boards."
13. Dr. Rupert Norton of Washington, D. C., "The Child's Brain as Illustrated by Recent Neurologic Studies."
14. Dr. F. T. Rogers of Providence, R. I., "The Ethical Advertiser."
15. Dr. J. T. Searcy of Tuscaloosa, Ala., "How Education Fails—Physiologically Considered."
16. Dr. Charles G. Stockton of Buffalo, "The Kindergarten."
17. Dr. James L. Taylor of Wheelersburg, Ohio, "The Amount of Work a Growing Brain Ought to Undertake."
18. Dr. Casey A. Wood of Chicago, "Kindergarten and Primary Grade Work in the Public Schools and its Influence upon the Eyesight."

There is room for the presentation of a few more papers. Fellows desiring to contribute are requested to send the titles to the Secretary promptly.

Many of these papers are planned for the discussion "The Physiologic Side of the Education of Youth," the special theme suggested for the meeting.

The Camden County Medical Society has sent the following letter to Hon. Herbert W. Johnson, Senator; Hons. William J. Bradley, John H. McMurray and Edgar J. Coles, Members of Assembly:

CAMDEN, N. J., Feb. 8, 1898.

Gentlemen:—In compliance with the instructions of the Camden County Medical Society, at a meeting held this day, the undersigned have the honor to call your attention to and to solicit your interest in Senate Bill No. 80, entitled "An Act to Establish a Village of Epileptics," introduced by Senator Daly and referred to the Committee on Miscellaneous Business.

The subject of segregating epileptics for industrial education and medical treatment was brought to the attention of the legislature of this State in 1896, and a bill was passed providing for the establishment of a colony for that purpose which, however, met with the disapproval of the Governor.

At the annual meeting of the Medical Society of New Jersey in 1897, the necessity for this measure furnished the subject of an address by the president, Dr. Thomas J. Smith of Bridgeton and a committee was appointed to present the matter to the legislature.

In emphasizing the importance of this measure, Dr. Smith stated that there were probably from 2000 to 3000 epileptics in this State, 500 of whom were doubtless confined in almshouses, asylums or in private families. These cases impose a heavy burden on the State and the family, and some of them are not infrequently a menace to the comfort and safety of society. Neither the hospital nor the asylum affords the proper conditions for their treatment, since an institution, to meet their highest needs, should possess the facilities for mental improvement, industrial education and physical development, as well as the advantages for medical treatment. These opportunities are afforded in the greatest degree by the colony system, and, where this system has been introduced, the percentage of cures has been materially increased.

The segregation of epileptics into colonies originated with the French in 1848, as stated by Dr. Smith, and the success of the system has led to its establishment in England, Germany

and other European countries. In this country, colonies have been or are now being established in Massachusetts, New York, Pennsylvania, Maryland, Ohio, Illinois, Iowa, Wisconsin, Minnesota and California.

It is an axiom in political economy that the prosperity of the State, rests, in no small degree, upon the physical welfare of her citizens; and in this era of unrivaled medical progress, New Jersey should not fall behind her sister States in the intelligent and beneficent care of her people.

With the hope that this measure may meet with your favorable consideration and active support, we have the honor to convey to you this Society's best esteem and to express at the same time the assurance of our high regard.

Very respectfully,

[Signed] E. L. B. GODFREY, M.D., } Committee.
WILLIAM H. ISZARD, M.D., }

PUBLIC HEALTH.

Personal.—Dr. William H. Welch of Johns Hopkins Hospital, has reconsidered his declination of membership in the Maryland State Board of Health, and accepted the appointment.

Compulsory Antitoxin.—According to the *Semaine Méd.* the Government of Bosnia and Herzegovina has rendered the use of diphtheria antitoxin compulsory, both as a curative and preventive.

The Bubonic Plague Still Prevailing.—The recent invasion of Sinner by the plague caused a riot by reason of the authorities having attempted isolation. The temporary hospitals were attacked, the quarantine camp set on fire, and the mob were dispersed only after the police had resorted to extreme measures. The reported deaths up to January 31 were forty-three.

Health in San Francisco.—The semi-annual report of the Health Department of the City and County of San Francisco, Cal., gives 3,000 deaths for the period from July 1, 1897, to Dec. 31, 1897. The greatest number of deaths occurred in November, viz., 581, and the least in December, viz., 138. The chief causes were: Phthisis pulmonalis, 427 deaths; heart disease, 385; pneumonia, 237; violence, 202; nephritis, 187; cancer, 179. In 257 cases of diphtheria reported there were 44 deaths and in 53 cases of scarlatina, 2 deaths.

Health in Michigan.—The report for January gives the ten diseases most prevalent during the month, as rheumatism, influenza, neuralgia, bronchitis, tonsillitis, pneumonia, pleuritis, diarrhea, inflammation of the kidney and erysipelas. Consumption was reported at 150 places; diphtheria, 73; measles, 63; scarlet fever, 61; typhoid fever, 57, and whooping cough at 31 places. As compared with the previous month, consumption, diphtheria, scarlet fever and typhoid fever, shows a decrease, while measles increased. Compared with the average for January, in the twelve years, 1886-1897, prevalence of consumption showed a marked decrease and remittent and intermittent fever a large decrease.

Health in Michigan during 1897.—From the report of the Michigan State Board of Health we glean the following: During the year 1897 action was taken on 124 more outbreaks of diphtheria than in 1896, 49 less of scarlet fever, 55 less of typhoid and typhomalarial fever, 332 more of measles, 76 less of whooping cough, 6 less of smallpox and 155 more of consumption. In all, 425 more outbreaks were acted on in 1897 than in 1896, and 66 more in 1896 than in 1895. Only two outbreaks of smallpox were reported during 1897, with but fifteen cases and no deaths.

Progress in Official Vaccination with Calf Lymph in England.—At a meeting of the Redruth (England) Board of Guardians, held in October last, a communication was read from the Local Government Board recommending that sixpence per case extra for vaccinations performed with calf lymph would be a sufficient remuneration for the medical officers. The Board added that the guardians themselves could not supply calf lymph except

in the case of an outbreak of smallpox. It was eventually resolved that sixpence be allowed in each case where calf lymph was used, although one guardian moved that only threepence should be given.

The Louisiana State Board of Health.—A new board has been appointed by Governor Foster to take the place of that which resigned about the first of this year. The membership of this board comprises men well known in the medical and business communities. The board is constituted as follows: Drs. Edmond Souchon, L. F. Reynaud, Luther Sexton, J. J. Castellanos and H. L. Lewis, and Messrs Stanley O. Thomas, J. D. Hill, Charles W. Castles and Jules C. Denis. These officers went on duty about February 1.

The Efficacy of Antitoxin is strikingly apparent in the official public health statistics recently published by the German Government for the years 1885 to 1895, the latter the first year when antitoxin came into general use. The mortality from diphtheria and croup was less by 49.48 per cent. than the average of the preceding years. The morbidity also showed a similar decrease, varying with the locality from 31.50 to 64.75 per cent. less than preceding years. The reports from Norway are still more conclusive. At Geneva also, the children in a large asylum were exposed to contagion and all but two received preventive inoculation. These two promptly succumbed while none of the rest were affected.

Health in New York During 1897. According to the *Monthly Bulletin* for December, the deaths reported during the year were 117,085, or 3,600 less than in 1896, being the smallest mortality since 1889. This makes the death rate for the year 18.50 per 1,000 population, while that of the two years preceding was 19.00. The death rate of the Maritime District was 18.90; Hudson Valley, 17.75; Adirondack and Northern, 14.50; Mohawk Valley, 16.00; Southern Tier, 14.00; East Central, 16.00; West Central, 14.50; Lake Ontario and Western, 15.25. The mortality has increased in rural parts, decreased in urban. Infant mortality is lower, 32.6 per cent. As to causes, compared with 1896 there were 1,500 less deaths from diarrheal diseases in 1897, 500 less from diphtheria, 600 less from measles, and a moderate increase in those from scarlet fever. The deaths from gripe early in the year were the same for both years, viz., 3,000. Consumption caused 10.8 per cent. of the whole mortality, or 12,638 deaths in 1897 against 13,265 in 1896.

Disinfection Work at New Orleans.—The board of Health of that city has been very diligently engaged in offering disinfection of domiciles and articles of clothing that have been brought within the range of yellow fever infection, during the late epidemic. The following are paragraphs taken from a circular of information that was prepared and published in the daily papers in December: "The board offers to perform the necessary work of disinfection, without charge, and with the least possible inconvenience to householders. The citizens of New Orleans are earnestly requested to second this effort of the board to free the city of any lingering trace of infection. Applications should be made in writing, and will receive attention in the order of their receipt. In view of the great value of thorough aeration as a means of purifying the interior of dwellings, it is respectfully suggested and urged that every opportunity be utilized to admit a copious supply of dry, cold air and plenty of sunshine into houses where sickness has occurred, and to so dispose bedding, clothing, etc., in such houses as to secure the full benefit of this plan of purification." *N. O. Medical and Surgical Journal*, February.

New York City Board of Health.—That Board having been put upon the defensive regarding its large production and sale of antitoxins and vaccines, it has caused to be prepared a showing, in the first place, of the excellent results that have flowed from its vaccination methods. For example, it is set forth that

since 1874, after the passage of a rule by the Board of Education providing that no pupil should be allowed to attend school nor any teacher employed unless vaccinated, not one pupil or teacher was afflicted with smallpox. President Straus also shows that in no other city in the State are vaccine virus and diphtheria antitoxin manufactured in such large quantities. The following table shows the diphtherial death rate since 1892:

Years.	Estimated Population.	Deaths by Diphtheria.	Rate of Mortality.
1892	1,708,124	2,106	1.23
1893	1,758,010	2,558	1.45
1894	1,809,353	2,870	1.59
1895	1,877,195	1,976	1.05
1896	1,934,077	1,763	.91
1897	1,990,562	1,591	.80

In 2450 cases treated with diphtheria anti-toxin by inspectors of the Board in 1895, 1896 and 1897, there were only 363 deaths. The cost of diphtheria antitoxin, as manufactured by the Board of Health, is \$1 an ounce. If purchased at drug stores it will cost \$12 an ounce. Manufacturing in large quantities made it possible to produce both vaccine virus and antitoxin at the lowest possible cost. Even at the large price charged by druggists it did not always follow that the vaccine and antitoxin sold by them were pure and fresh.
